The major challenge with assessing natural language input is that it is relatively unconstrained and rarely follows brittle rules in its computation of spelling, syntax, and semantics (McCarthy et al., 2007). Researchers who have developed tutorial dialogue systems in natural language have explored the accuracy of matching students' written input to targeted knowledge. Examples of these systems are AutoTutor and Why-Atlas, which tutor students on Newtonian physics (Graesser, Olney, Haynes, & Chipman, 2005; VanLehn, Graesser, et al., 2007), and the iSTART system, which helps students read text at deeper levels (McNamara, Levinstein, & Boonthum, 2004). Systems such as these have typically relied on statistical representations, such as latent semantic analysis (LSA; Landauer, McNamara, Dennis, & Kintsch, 2007) and content word overlap metrics (McNamara, Boonthum, et al., 2007). Indeed, such statistical and word overlap algorithms can boast much success. However, over short dialogue exchanges (such as those in ITSs), the accuracy of interpretation can be seriously compromised without a deeper level of lexico-syntactic textual assessment (McCarthy et al., 2007). Such a lexico-syntactic approach, *entailment evaluation*, is presented in this chapter. The approach incorporates deeper natural language processing solutions for ITSs with natural language exchanges while

remaining sufficiently fast to provide real time assessment of user input.

BACKGROUND

Entailment evaluations help in the assessment of the appropriateness of student responses during ITS exchanges. Entailment can be distinguished from three similar terms (implicature, paraphrase, and elaboration), all of which are also important for assessment in ITS environments (McCarthy et al, 2007).

The terms *entailment* is often associated with the highly similar concept of *implicature*. The distinction is that entailment is reserved for linguistic-based inferences that are closely tied to *explicit* words, syntactic constructions, and formal semantics, as opposed to the knowledge-based *implied* referents and references, for which the term *implicature* is more appropriate (McCarthy et al., 2007). *Implicature* corresponds to the controlled knowledge-based elaborative inferences defined by Kintsch (1993) or to knowledge-based inferences defined in the inference taxonomies in discourse psychology (Graesser, Singer, & Trabasso, 1994).

The terms *paraphrase* and *elaboration* also need to be distinguished from entailment. A *paraphrase* is a reasonable restatement of the text. Thus, a paraphrase is a form of entailment, yet an entailment is not necessarily a paraphrase. This asymmetric relation can be understood if we consider that *John went to the store* is entailed by (but not a paraphrase of) *John drove to the store to buy supplies*. The term *elaboration* refers to information that is generated inferentially or associatively in response to the text being analyzed, but without the systematic and sometimes formal constraints of entailment, implicature, or paraphrase. Examples of each term are provided below for the sentence *John drove to the store to buy supplies*.

Entailment: *John went to the store.*
(Explicit, logical implication based on the text)

Implicature: *John bought some supplies.*
(Implicit, reasonable assumption from the text, although not explicitly stated in the text)

Paraphrase: *He took his car to the store to get things that he wanted.*

(Reasonable re-statement of all and only the critical information in the text)

Elaboration: *He could have borrowed stuff.*
(Reasonable *reaction* to the text)

Evaluating entailment is generally referred to as the task of *recognizing textual entailment* (RTE; Dagan, Glickman, & Magnini, 2005). Specifically, it is the task of deciding, given two text fragments, whether the meaning of one text logically infers the other. When it does, the evaluation is deemed as T (the entailing text) entails H (the entailed hypothesis). For example, a text (from the RTE data) of *Eyeing the huge market potential, currently led by Google, Yahoo took over search company Overture Services Inc last year* would entail a hypothesis of *Yahoo bought Overture*. The task of recognizing entailment is relevant to a large number of applications, including machine translation, question answering, and information retrieval.

The task of textual entailment has been a priority in investigations of information retrieval (Monz & de Rijke, 2001) and automated language processing (Pazienza, Pennacchiotti, & Zanzotto, 2005). In related work, Moldovan and Rus (2001) analyzed how to use unification and matching to address the *answer correctness* problem. Similar to entailment, *answer correctness* is the task of deciding whether candidate answers logically imply an ideal answer to a question.

THE LEXICO-SYNTACTIC ENTAILMENT APPROACH

A complete solution to the textual entailment challenge requires linguistic information, reasoning, and world knowledge (Rus, McCarthy, McNamara, & Graesser, in press). This chapter focuses on the role of linguistic information in making entailment decisions. The overall goal is to produce a light (i.e. computationally inexpensive), but accurate solution that could be used in interactive systems such as ITSs. Solutions that rely on processing-intensive deep representations (e.g., frame semantics and reasoning) and large structured repositories of information (e.g., ResearchCyc) are impractical for interactive tasks because they result in lengthy response times, causing user dissatisfaction.

One solution for recognizing textual entailment is based on subsumption. In general, an object X subsumes

an object Y if and only if X is more general than or identical to Y. Applied to textual entailment, subsumption translates as follows: hypothesis H is entailed from T if and only if T subsumes H. The solution has two phases: (I) map both T and H into graph structures and (II) perform a subsumption operation between the T-graph and H-graph. An entailment score, $\text{entail}(T, H)$, is computed, quantifying the degree to which the T-graph subsumes the H-graph.

In *phase I*, the two text fragments involved in a textual entailment decision are initially mapped onto a graph representation. The graph representation employed is based on the dependency-graph formalisms of Mel'cuk (1998). The mapping relies on information from syntactic parse trees. A phrase-based parser is used to derive the dependencies. Although a dependency-parser may be adopted, our particular research agenda required partial phrase parsers for other tasks such as computing cohesion metrics. Having a phrase-based and dependency parser integrated in the system would have led to a heavier, less interactive system. A parse tree groups words into phrases and organizes these phrases into hierarchical tree structures from which syntactic dependencies among concepts can be detected. The system uses Charniak's (2000) parser to obtain parse trees and Magerman's (1994) head-detection rules to obtain the head of each phrase. A dependency tree is generated by linking the head of each phrase to its modifiers in a systematic mapping process. The dependency tree encodes exclusively local dependencies (head-modifiers), as opposed to long-distance (remote) dependencies, such as the remote subject relation between *bombers* and *enter* in the sentence *The bombers managed to enter the embassy compounds*. Thus, in this stage, the dependency tree is transformed onto a *dependency graph* by generating *remote dependencies* between content words. Remote dependencies are computed by a naive-Bayes functional tagger (Rus

& Desai, 2005). An example of a dependency graph is shown in Figure 1 for the sentence *The two objects will cover the same horizontal distance*. For instance, there is a subject (*subj*) dependency relation between *objects* and *cover*.

In *phase II*, the textual entailment problem (i.e., each T and H) is mapped into a specific example of graph isomorphism called *subsumption* (also known as *containment*). Isomorphism in graph theory addresses the problem of testing whether two graphs are the same.

A graph $G = (V, E)$ consists of a set of nodes or *vertices* V and a set of *edges* E. Graphs can be used to model the linguistic information embedded in a sentence: vertices represent concepts (e.g., *bombers*, *joint venture*) and edges represent syntactic relations among concepts (e.g., the edge labeled *subj* connects the verb *cover* to its subject *objects* in Figure 1). The Text (T) entails the Hypothesis (H) if and only if the hypothesis graph is subsumed (or contained) by the text graph.

The subsumption algorithm for textual entailment (Rus et al., in press) has three major steps: (1) find an isomorphism between V_H (set of vertices of the Hypothesis graph) and V_T ; (2) check whether the labeled edges in H, E_H , have correspondents in E_T ; and (3) compute score. In step 1, for each vertex V_H , a correspondent V_T node is sought. If a vertex in H does not have a direct correspondent in T, a thesaurus is used to find all possible synonyms for vertices. Step 2 takes each relation in H and checks its presence in T. The checking is augmented with relation equivalences among linguistic phenomena such as possessives and linking verbs (e.g. *be*, *have*). For instance, *tall man* would be equivalent to *man is tall*. A normalized score for vertices and edge mapping is then computed. The score for the entire entailment is the sum of each individual vertex and edge matching score. Finally, the score must account for negation. The approach handles both *explicit* and *implicit* negation. Explicit negation is indicated by particles such as *no*, *not*, *neither ... nor*

Figure 1. An example of a dependency graph

and the shortened form *n't*. Implicit negation is present in text via deeper lexico-semantic relations among linguistic expressions. The most obvious example is the *antonymy* relation among words, which is retrieved from WordNet (Miller, 1995). Negation is accommodated in the score after making the entailment decision for the Text-Hypothesis pair (without negation). If any one of the text fragments is negated, the decision is reversed, but if both are negated the decision is retained (double-negation), and so forth.

Entailment for Intelligent Tutoring Systems

The problem of evaluating student input in ITSs with natural language understanding is modeled here as a textual entailment problem. Results of this approach are shown on data sets from two ITSs: AutoTutor and iSTART. Data from the AutoTutor experiments involve college students learning Newtonian physics, whereas data from iSTART involve adolescent and college students constructing explanations about science texts.

AutoTutor

AutoTutor (autotutor.org) teaches topics such as Newtonian physics, computer literacy, and critical thinking by holding a dialogue in natural language with the student. The system presents deep-reasoning questions to the student that call for explanations or other elaborate answers. AutoTutor has a list of anticipated good answers (or *expectations*) and a list of *misconceptions* associated with each main question. AutoTutor guides the student in articulating the expectations through a number of dialogue moves and adaptively responds to the student by giving short *feedback* on the quality of student contributions.

To understand how the entailment approach helps to assess the appropriateness of student responses in AutoTutor, consider the following AutoTutor problem:

Suppose a runner is running in a straight line at constant speed, and the runner throws a pumpkin straight up. Where will the pumpkin land? Explain why.

An expectation for this problem is *The object will continue to move at the same horizontal velocity as the person when it is thrown*. A real student answer is *The pumpkin and the runner have the same horizontal*

velocity before and after release. The expert judgment of this response was *very good*. Such *expectation/student-input* (E-S) pairs can be viewed as an entailment pair of Text-Hypothesis. The task is to find the truth value of the student answer based on the true fact encoded in the expectation. Rus and Graesser (2006) examined how the lexico-syntactic system described in the previous section performed on a test set of 125 E-S pairs collected from a sample of AutoTutor tutorial dialogues. The lexico-syntactic approach provided the best accuracy (69%), whereas a Latent Semantic Analysis (LSA, Landauer et al., 2007) approach yielded an accuracy of 60%. Such a result illustrates the value of augmenting AutoTutor with lexico-syntactic natural language understanding.

iSTART (Interactive Strategy Trainer for Active Reading and Thinking)

The primary goal of iSTART (istartreading.com) is to help high school and college students learn to use reading comprehension strategies that support deeper understanding. iSTART's design combines the power of self-explanation in facilitating deep learning (McNamara et al., 2004) with content-sensitive, interactive strategy training. The iSTART system helps students learn to self-explain using a variety of reading strategies (e.g., rewording the text, or *paraphrasing*; or *elaborating* on the text by linking textual content to what the reader already knows). The final stage of the iSTART process requires students to self-explain sentences from two short passages. Scaffolded feedback is provided to the students based on the quality of the student responses.

The entailment evaluation has been used in two iSTART studies. In Rus et al. (2007), a corpus of iSTART self-explanation responses was evaluated by an array of textual evaluation measures. The results demonstrated that the entailment approach was the most powerful distinguishing index of the self-explanation categories (Entailer: $F(1,1228) = 25.05, p < .001$; LSA: $F(1,1228) = 2.98, p > .01$). In McCarthy et al. (2007), iSTART self explanations were hand-coded for degree of entailment, paraphrase, versus elaboration. Once again, the entailment evaluation proved to be a more powerful predictor of these categories than traditional measures: for *entailment*, the Entailer was a significant predictor ($t = 9.61, p < .001$) and LSA was a marginal predictor ($t = -1.90, p = .061$); for *elaboration* and for

paraphrase the Entailer was again a significant predictor ($t = -7.98, p < .001$; $t = 5.62, p < .001$, respectively), whereas LSA results were not significant.

FUTURE TRENDS

While the results of the entailment evaluation have been encouraging, a variety of developments of the approach are underway. For example, there are plans to weight words by their specificity and to learn syntactic patterns or transformations that lead to similar meanings. The current negation detection algorithm will be extended to assess plausible implicit forms of negation in words such as *denied*, *denies*, *without*, *ruled out*. A second extension addresses issues of relative opposites: knowing that an object is *not* hot does not entail that the object is cold (i.e., it could simply be warm).

CONCLUSION

Recognizing and assessing textual entailment is a prominent and challenging task in the fields of Natural Language Processing and Artificial Intelligence. This chapter presented a lexico-syntactic approach to the task of evaluating entailment. The approach is light, using minimal knowledge resources, yet it has delivered high performance in evaluations of three data sets involving natural language interactions in ITSs. The entailment approach is a promising step in achieving the goal of fast and effective evaluation of student contributions in short text exchanges, which is needed to provide optimal feedback and responses to student learners.

KEY TERMS

Dependency: Binary relations between words in a sentence whose label indicates the syntactic relation among the two words.

Entailment: The task of deciding whether a text fragment logically or semantically infers another text fragment.

Expectation: A stored (generally *ideal*) answer to a problem, against which input is evaluated; concept used in ITSs.

Graph Subsumption: A specific example of graph isomorphism. Isomorphism exists when two graphs are equivalent. Subsumption can be viewed as subgraph isomorphism.

Intelligent Tutoring System: Interactive, feedback-based computer systems designed to help students learn various topics.

Latent Semantic Analysis: A statistical technique for human language understanding based on words that co-occur in documents of large corpora.

Natural Language Processing: The science of capturing the meaning of human language in computational representations and algorithms.

Natural Language Understanding and Assessment: An NLP subset focusing on evaluating natural language input in intelligent tutoring systems.

Syntactic Parsing: The process of discovering the underlying structure of sentences.

Navigation by Image-Based Visual Homing

Matthew Szenher

University of Edinburgh, UK

INTRODUCTION

Almost all autonomous robots need to navigate. We define navigation as do Franz & Mallot (2000): “Navigation is the process of determining and maintaining a course or trajectory to a goal location” (p. 134). We allow that this definition may be more restrictive than some readers are used to - it does not for example include problems like obstacle avoidance and position tracking - but it suits our purposes here.

Most algorithms published in the robotics literature localise in order to navigate (see e.g. Leonard & Durrant-Whyte (1991a)). That is, they determine their own location and the position of the goal in some suitable coordinate system. This approach is problematic for several reasons. Localisation requires a map of available landmarks (i.e. a list of landmark locations in some suitable coordinate system) and a description of those landmarks. In early work, the human operator provided the robot with a map of its environment. Researchers have recently, though, developed simultaneous localisation and mapping (SLAM) algorithms which allow robots to learn environmental maps while navigating (Leonard & Durrant-Whyte (1991b)). Of course, autonomous SLAM algorithms must choose which landmarks to map and sense these landmarks from a variety of different positions and orientations. Given a map, the robot has to associate sensed landmarks with those on the map. This data association problem is difficult in cluttered real-world environments and is an area of active research.

We describe in this chapter an alternative approach to navigation called visual homing which makes no explicit attempt to localise and thus requires no landmark map. There are broadly two types of visual homing algorithms: feature-based and image-based. The feature-based algorithms, as the name implies, attempt to extract the same features from multiple images and use the change in the appearance of corresponding features to navigate. Feature correspondence is - like data association - a difficult, open problem in real-world environments. We argue that image-based homing algorithms, which

provide navigation information based on whole-image comparisons, are more suitable for real-world environments in contemporary robotics.

BACKGROUND

Visual homing algorithms make no attempt to localise in order to navigate. No map is therefore required. Instead, an image I_s (usually called a snapshot for historical reasons) is captured at a goal location $S = (x_s, y_s)$. Note that though S is defined as a point on a plane, most homing algorithms can be easily extended to three dimensions (see e.g. Zeil et al. (2003)). When a homing robot seeks to return to S from a nearby position $C = (x_c, y_c)$, it takes an image I_c and compares it with I_s . The home vector $\mathbf{H} = S - C$ is inferred from the disparity between I_s and I_c (vectors are in upper case and bold in this work). The robot's orientation at C and S is often different; if this is the case, image disparity is meaningful only if I_c is rotated to account for this difference. Visual homing algorithms differ in how this disparity is computed.

Visual homing is an iterative process. The home vector \mathbf{H} is frequently inaccurate, leading the robot closer to the goal position but not directly to it. If \mathbf{H} does not take the robot to the goal, another image I_c is taken at the robot's new position and the process is repeated.

The images I_s and I_c are typically panoramic gray-scale images. Panoramic images are useful because, for a given location (x, y) they contain the same image information regardless of the robot's orientation. Most researchers use a camera imaging a hemispheric, conical or paraboloid mirror to create these images (see e.g. Nayar (1997)).

Some visual homing algorithms extract features from I_s and I_c and use these to compute image disparity. Alternatively, disparity can be computed from entire images, essentially treating each pixel as a viable feature. Both feature-based and image-based visual homing algorithms are discussed below.

FEATURE-BASED VISUAL HOMING

Feature-based visual homing methods segment I_S and I_C into features and background (the feature extraction problem). Each identified feature in the snapshot is then usually paired with one feature in I_C (the correspondence problem). The home vector is inferred from - depending on the algorithm - the change in the bearing and/or apparent size of the paired features. Generally, in order for feature-based homing algorithms to work properly, they must reliably solve the feature extraction and correspondence problems.

The Snapshot Model (Cartwright & Collett (1983)) - the first visual homing algorithm to appear in the literature and the source of the term “snapshot” to describe the goal image - matches each snapshot feature with the current feature closest in bearing (after both images are rotated to the same external compass orientation). Features in (Cartwright & Collett (1983)) were black cylinders in an otherwise empty environment. Two unit vectors, one radial and the other tangential, are associated with each feature pair. The radial vector is parallel to the bearing of the snapshot feature; the tangential vector is perpendicular to the radial vector. The direction of the radial vector is chosen to move the agent so as to reduce the discrepancy in apparent size between paired features. The direction of the tangential vector is chosen to move the agent so as to reduce the discrepancy in bearing between paired features. The radial and tangential vectors for all feature pairs are averaged to produce a homing vector. The Snapshot Model was devised to explain the behaviour of nest-seeking honeybees but has inspired several robotic visual homing algorithms.

One such algorithm is the Average Landmark Vector (ALV) Model (Möller et al. (2001)). The ALV Model, like the Snapshot Model, extracts features from both I_C and I_S . The ALV Model, though, does not explicitly solve the correspondence problem. Instead, given features extracted from I_S , the algorithm computes and stores a unit vector ALV_S in the direction of the mean bearing to all features as seen from S . At C , the algorithm extracts features from I_C and computes their mean bearing, encoded in the unit vector ALV_C . The home vector \vec{H} is defined as $ALV_C - ALV_S$. Figure 1 illustrates home vector computation for a simple environment with four easily discernible landmarks.

Several other interesting feature-based homing algorithms can be found in the literature. Unfortunately, space constraints prevent us from reviewing them here.

Two algorithms of note are: visual homing by “surfing the epipoles” (Basri et al. (1998) and the Proportional Vector Model (Lambrinos et al. (2000)).

The Snapshot and ALV Models were tested by their creators in environments in which features contrasted highly with background and so were easy to extract. How is feature extraction and correspondence solved in real-world cluttered environments? One method is described in Gourichon et al. (2002). The authors use images converted to the HSV (Hue-Saturation-Value) colour space which is reported to be more resilient to illumination change than RGB. Features are defined as image regions of approximately equal colour (identified using a computationally expensive region-growing technique). Potential feature pairs are scored on their difference in average hue, average saturation, average intensity and bearing. The algorithm searches for a set of pairings which maximise the sum of individual match scores. The pairing scheme requires $O(n^2)$ pair-score computations (where n is the number of features). The algorithm is sometimes fooled by features with similar colours (specifically, pairing a blue chair in the snapshot image with a blue door in the current image). Gourichon et al. did not explore environments with changing lighting conditions.

Several other methods feature extraction and correspondence algorithms appear in the literature; see e.g. Rizzi et al. (2001), Lehrer & Bianco (2000) and Gaussier et al. (2000). Many of these suffer from some of the same problems as the algorithm of Gourichon et al. described above. The appearance of several competing feature extraction and correspondence algorithms in recent publications indicates that these are open and difficult problems; this is why we are advocating image-based homing in this chapter.

Figure 1. Illustration of Average Landmark Vector computation. See Section titled “Feature-based Visual Homing” for details

IMAGE-BASED VISUAL HOMING

Feature-based visual homing algorithms require consistent feature extraction and correspondence over a variety of viewing positions. Both of these are still open problems in computer vision. Existing solutions are often computationally intensive. Image-based visual homing algorithms avoid these problems altogether. They infer image disparity from entire images; no pixel is disregarded. We believe that these algorithms present a more viable option for real-world, real-time robotics.

Three image-based visual homing algorithms have been published so far; we describe these below.

Image Warping

The image warping algorithm (Franz et al. (1998)) asks the following question: When the robot is at C in some unknown orientation, what change in orientation and position is required to transform I_C into I_S ? The robot needs to know the distance to all imaged objects in I_S to answer this question precisely. Not having this information, the image warping algorithm makes the assumption that all objects are at an equal (though unknown) distance from S . The algorithm searches for the values of position and orientation change which minimises the mean-square error between a transformed I_C and I_S . Since the mean square error function is rife with local minima, the authors resort to a brute force search over all permissible values of position and orientation change.

Unlikely as the equal distance assumption is, the algorithm frequently results in quite accurate values for H . Unlike most visual homing schemes, image warping requires no external compass reference. Unfortunately, the brute force search for the homing vector and the large number of transformations of I_C carried out during this search make image warping quite computationally expensive.

Homing with Optic Flow Techniques

When an imaging system moves from S to C , the image of a particular point in space moves from $I_S(x, y)$ to $I_C(x', y')$. This movement is called optic flow and $(x - x', y - y')$ is the so called pixel displacement vector. Vardy & Möller (2005) demonstrate that the home vector H can be inferred from a single displacement vector so long as the navigating robot is constrained to move on

a single plane. Several noisy displacement vectors can be combined to estimate H .

Vardy & Möller (2005) describe a number of methods, adapted from the optic flow literature, to estimate the displacement vector. One of the most successful methods – BlockMatch – segments the snapshot image into several equal-sized subimages. The algorithm then does a brute force search of a subset of I_C to find the best match for each subimage. A displacement vector is computed from the centre of each subimage to the centre of its match pair in I_C .

A less computationally intensive algorithm estimates the displacement vector from the intensity gradient at each pixel in I_C . The intensity gradient at a particular pixel can be computed straightforwardly from intensities surrounding that pixel. No brute-force search is required.

In comparative tests, Vardy & Möller demonstrated that their optic flow based methods perform consistently better than image warping in several unadulterated indoor environments. A drawback to the optic flow homing methods is that the robot is constrained to move on a single plane. The authors do not provide a way to extend their algorithm to three dimensional visual homing.

Surfing the Difference Surface

Zeil et al. (2003) describe a property of natural scenes which can be exploited for visual homing: as the Euclidean distance between S and C increases, the pixel-by-pixel root mean square (RMS) difference between I_S and I_C increases smoothly and monotonically. Labrosse and Mitchell discovered this phenomenon as well; see Mitchell & Labrosse (2004). Zeil et al. reported that the increase in the RMS signal was discernible from noise up to about three meters from S in their outdoor test environment; they call this region the catchment area.

RMS, when evaluated at locations in a subset of the plane surrounding S , forms a mathematical surface, the difference surface. A sample difference surface is shown in Figure 2(a) (see caption for details).

Zeil et al. describe a simple algorithm to home using the RMS difference surface. Their “Run-Down” algorithm directs the robot to move in its current direction while periodically sampling the RMS signal. When the current sample is greater than the previous, the robot is made to stop and turn ninety degrees (clockwise or

Figure 2. Two difference surfaces formed using the RMS image similarity measure. Both the surfaces and their contours are shown. In each case, the snapshot I_s was captured at $x=150\text{cm}$, $y=150\text{cm}$ in a laboratory environment. (a) The snapshot was captured in the same illumination conditions as all other images. Notice the global minimum at the goal location and the absence of local minima. (b) Here we use the same snapshot image as in (a) but the lighting source has changed in all other images. The global minimum no longer appears at the goal location. When different goal locations were used, we observed qualitatively similar disturbances in the difference surfaces formed. The images used were taken from a database provided by Andrew Vardy which is described in Vardy & Möller (2005).

counter-clockwise, it does not matter). It then repeats the process in this new direction. The agent stops when the RMS signal falls below a pre-determined threshold. We have explored a biologically inspired difference surface homing method which was more successful than “Run-Down” in certain situations (Zampoglou et al. (2006)).

Unlike the optic flow methods described in the previous section, visual homing by optimising the difference surface is easily extensible to three dimensions (Zeil et al. (2003)).

Unfortunately, when lighting conditions change between capture of I_s and I_c , the minimum of the RMS difference surface often fails to coincide with S , making homing impossible (Figure 2(b)).

FUTURE TRENDS

No work has yet been published comparing the efficacy of the image-based homing algorithms described above. This would seem the logical next step for image-based homing researchers. As we mentioned in the section titled “Surfing the Difference Surface,” the difference surface is disrupted by changes in lighting between captures of I_s and I_c . This problem obviously demands a solution and is a focus of our current research. Finally, it would be interesting to compare standard map-based navigation algorithms with the image-based visual homing methods presented here.

CONCLUSION

Visual homing algorithms - unlike most of the navigation algorithms found in the robotics literature - do not require a detailed map of their environment. This is because they make no attempt to explicitly infer their location with respect to the goal. These algorithms instead infer the home vector from the discrepancy between a stored snapshot image taken at the goal position and an image captured at their current location.

We reviewed two types of visual homing algorithms: feature-based and image-based. We argued that image-based algorithms are preferable because they make no attempt to solve the tough problems of consistent feature extraction and correspondence - solutions to which feature-based algorithms demand. Of the three

image-based algorithms reviewed, image warping is probably not practicable due to the computationally demanding brute force search required. Work is required to determine which of the two remaining image-based algorithms is more effective for robot homing in real-world environments.

KEY TERMS

Catchment Area: The area from which a goal location is reachable using a particular navigation algorithm.

Correspondence Problem: The problem of pairing an imaged feature extracted from one image with the same imaged feature extracted from a second image. The images may have been taken from different locations, changing the appearance of the features.

Image-based Visual Homing: Visual homing (see definition below) in which the home vector is estimated from the whole-image disparity between snapshot and current images. No feature extraction or correspondence is required.

Feature Extraction Problem: The problem of extracting the same imaged features from two images taken from (potentially) different locations.

Navigation: The process of determining and maintaining a course or trajectory to a goal location.

Optic Flow: The perceived movement of objects due to viewer translation and/or rotation.

Snapshot Image: In the visual homing literature, this is the image captured at the goal location.

Visual Homing: A method of navigating in which the relative location of the goal is inferred by comparing an image taken at the goal with the current image. No landmark map is required.

Nelder–Mead Evolutionary Hybrid Algorithms

Sanjoy Das

Kansas State University, USA

N

INTRODUCTION

Real world optimization problems are often too complex to be solved through analytic means. Evolutionary algorithms are a class of algorithms that borrow paradigms from nature to address them. These are stochastic methods of optimization that maintain a population of individual solutions, which correspond to points in the search space of the problem. These algorithms have been immensely popular as they are derivative-free techniques, are not as prone to getting trapped in local minima, and can be tailored specifically to suit any given problem. The performance of evolutionary algorithms can be improved further by adding a local search component to them. The Nelder-Mead simplex algorithm (Nelder & Mead, 1965) is a simple local search algorithm that has been routinely applied to improve the search process in evolutionary algorithms, and such a strategy has met with great success.

In this article, we provide an overview of the various strategies that have been adopted to hybridize two well-known evolutionary algorithms - genetic algorithms (GA) and particle swarm optimization (PSO).

BACKGROUND

Arguably, GAs are one of the most of all common population based approaches for optimization. The population of candidate solutions that these algorithms maintain in each generation are called chromosomes. GAs carry out the Darwinian operators of selection, mutation, and recombination, on these chromosomes, to perform their search (Mitchell, 1998). Each generation is improved by removing the poorer solutions from the population, while retaining the better ones, based on a fitness measure. This process is called selection. Following selection, a method of recombining solutions called crossover is applied. Here two (or more) parent solutions from the current generation are picked randomly for producing offspring to populate the next generation of solutions. The offspring chromosomes

are then probabilistically subject to mutation, which is carried out by the addition of small random perturbations.

PSO is a more recent approach for optimization (Kennedy & Eberhart, 2001). Being modelled after the social behavior of organisms such as a flock of birds in flight or a school of fish swimming, it is considered an evolutionary algorithm only in a loose sense. Each solution within the population is called a particle in PSO. Each such particle's position in the search space is constantly updated within each generation, by the addition of the particle's velocity to it. The velocity of a particle is then adjusted towards the best position encountered in the particle's own history (individual best), as well as the best position in the current iteration (global best).

Since evolutionary algorithms use a population of individuals and randomized variational operators, they are adept at performing exploratory searches over their search spaces. However, when the aim is to produce outputs within reasonable time limits, it is important to balance this exploration with better exploitation of smaller-scale features in the fitness landscape. In the latter context, local search algorithms enable single solutions to be improved using local information (e.g., directional trends in fitness around each solution) and take the solution towards the closest maximum fitness. Hybrid algorithms that combine the advantages of exploration and exploitation comprise of a distinct area of evolutionary computation research that have been variously called as Lamarckian or memetic approaches, of which Nelder-Mead hybrids are a significant chunk.

NELDER-MEAD SIMPLEX BASED HYBRIDIZATION

The Nelder-Mead Downhill Simplex Algorithm

The Nelder-Mead simplex algorithm is a derivative-free local search technique that is capable of moving a cluster

Figure 1. Various operations in the Nelder-Mead simplex routine

of solutions in the gradient direction and which, as per current research, can be very effectively combined with GA and PSO approaches. These hybrid evolutionary algorithms have been shown to be very successful in continuous optimization problems.

The Nelder-Mead simplex method makes use of a construct called a simplex (see Figure 1.). When the search space is n -dimensional, the simplex consists of $n+1$ solutions, $s_i, i = \{1, 2, \dots, n+1\}$, that are usually closely spaced. As shown in the top left of Figure 1., in a two-dimensional search plane, a simplex is a triangle. The fitness of each solution is considered in each step of the Nelder-Mead method, and the worst solution w is identified. The centroid, c , of the remaining n points

$$c = \frac{1}{n} \sum s_i,$$

is computed and the reflection of w along it determined. This reflection yields a new solution r that replaces w , in the next step, as shown in the top right of Figure 1. If the solution r produced by this reflection has a higher fitness than any other solution in the simplex, the simplex is further expanded along the direction of

r , as shown in the middle left of the figure. On the other hand, if r has a low fitness compared to the others, the simplex is contracted. Contraction can be either outward or inward depending upon whether r is better or worse than w . The contraction operations are shown in the middle right and bottom left of the figure. If neither contraction improves the worst solution in the simplex, the best point in the simplex is computed, and a collapse is then carried out, and all the points of the simplex are moved a little closer towards the best one, as shown in the bottom right of the same figure.

The approaches taken to incorporate a simplex-based local search routine within the broad framework of a genetic algorithm fall under four different schemes that are shown in Figure 2. These are as follows:

Two-Phase Hybridization

This is the simplest of all approaches and has been applied to GAs (Chelouah & Siarry, 2000, Chelouah & Siarry, 2003, Robin, Orzati, Moreno, Homan & Bachtold, 2003). In the first phase in this scheme, a GA is applied to the optimization problem to explore the entire search space until one or more good solutions

are found, which can no longer be improved through the random operations of crossover and mutation. The Nelder-Mead simplex algorithm is then invoked in the second phase to further improve the solutions by allowing them to ascend towards their local maxima. In another approach the initial points of the simplex are obtained by taking the solution with the best fitness given by the GA, and then generating the remaining n points around it (Chelouah & Siarry, 2000, Chelouah & Siarry, 2003).

Serial Hybridization

In this scheme, the solutions in each generation are subject to the usual operators of the main evolutionary algorithm as well as the one or more steps of the Nelder-Mead simplex method. It has been successfully applied to hybridize GAs (Renders & Flasse, 1998, Yang & Douglas, 1998, Durand & Alliot, 1999, Guo & Shouyi, 2003, Trabia, 2004). This method has also been used in conjunction with PSO by Das *et al.* (Das, Koduru, Welch, Gui, Cochran, Wareing & Babin, 2006, Koduru, Welch, Das, 2007). In each generation, following the position and velocity updates, the population is

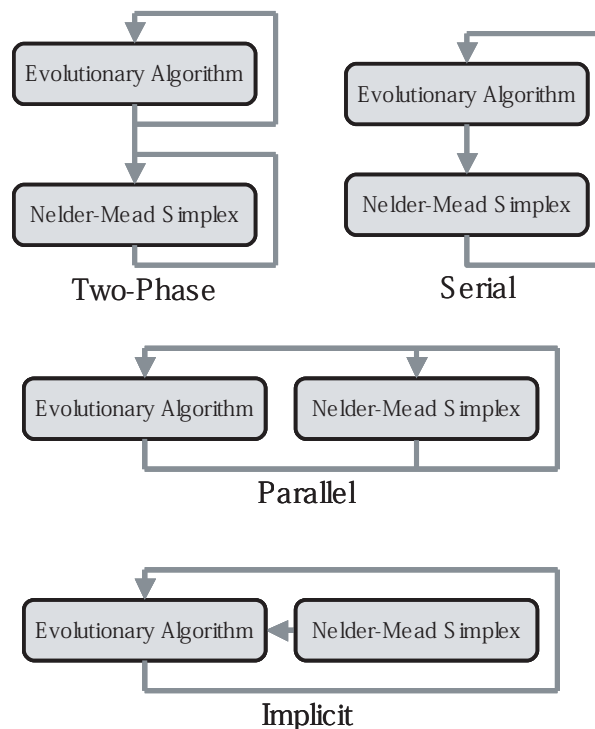

clustered into distinct clusters of $n+1$ solutions each, and a few steps of the Nelder-Mead algorithm applied separately to each cluster. The Nelder-Mead step is applied a fixed number of times per generation.

The serial hybridization scheme has been successfully implemented within a multi-objective optimization framework also (Koduru, Das, Welch 2007). Instead of fitness, a metric called fuzzy dominance is applied to discriminate between the $n+1$ solutions within a simplex. A solution that is not dominated by any other is assigned a fuzzy dominance of zero. The poorer a solution is, the higher the fuzzy dominance value it is assigned.

Parallel Hybridization

Such hybridization approaches assemble the offspring generation from the parent generation in two parallel tracks. The standard evolutionary algorithm operators are used to generate some of the offspring, while others are generated using the simplex algorithm. This strategy is applied to hybridize GAs (Yen, Liao, Lee & Randolph, 1998, Koduru, Das, Welch & Roe, 2004, Koduru, Das, Welch, Roe & Lopez-Dee, 2005). In these

Figure 2. Four different GA-simplex hybridization strategies

approaches, the best $n+1$ solutions (called elites) of each generation are picked to be improved further, using the Nelder-Mead simplex method. In another strategy, a probabilistic variant of the Nelder-Mead approach is used, where the amount of contraction and/or expansion of the simplex is determined randomly, but within specific limits (Yen, Liao, Lee & Randolph, 1998). The approaches taken in (Koduru, Das, Welch & Roe, 2004) and (Koduru, Das, Welch, Roe & Lopez-Dee, 2005) are multi-objective implementations that make use of the fuzzy dominance metric discussed earlier to identify the best and worst solutions. In order to preserve solution diversity within the population, the collapse operation is never used and the Nelder-Mead routine is terminated instead, when the need for one arises, within each generation.

This scheme has been used with PSO (Fan, Liang & Zahara 2004, Zahara, Fan & Tsai, 2005). As earlier, only the best $n+1$ points of the population are picked to undergo improvement using the Nelder-Mead simplex method. The remaining solutions in each generation are obtained using standard PSO position and velocity updates.

Implicit Hybridization

Here, the Nelder-Mead simplex algorithm is not applied directly. Instead, the approach is buried implicitly within any of the evolutionary algorithm's generic operators. One simple technique in GAs is the multi-parent simplex-based crossover (Renders & Bersini, 1994). This method applies a single Nelder-Mead step to produce a new offspring. Novel crossover techniques are also suggested (Bersini, 2002). In another method, each simplex is encoded as a chromosome and the algorithm uses a specially devised multi-parent crossover within the GA (Hedar & Fukushima, 2003).

Das *et al.* (Das, Koduru, Welch, Gui, Cochran, Wareing & Babin, 2006) use implicit hybridization in PSO by adding a term to the velocity of each particle that allows the latter to reorient its trajectory towards gradient direction sensed by the Nelder-Mead simplex (from the worst towards the centroid).

FUTURE TRENDS

Although traditionally, evolutionary algorithms have focussed on optimizing single objective functions,

most practical problems in engineering are inherently multi-objective in nature. Consequently, multi-objective evolutionary optimization is a relatively new, emerging direction of evolutionary computation research. Perhaps the only attempts at incorporating Nelder-Mead simplex as an additional operator within a GA have been reported by Koduru, Das & Welch (*cf.* Koduru, Das, Welch, Roe, 2004). Clearly more research is required in this direction, and as multi-objective algorithms become more common, Nelder-Mead strategies will be investigated more vigorously.

PSO is a new technique for evolutionary optimization. Research into PSO-based hybrid algorithms has only recently begun to make its appearance. A few limited approaches have been suggested to hybridize PSO with Nelder-Mead simplex by Das *et al.* (Das, Koduru, Welch, Gui, Cochran, Wareing & Babin, 2006) and Zahara *et al.*, (Zahara, Fan & Tsai, 2005). The method suggested in (Koduru, Das, Welch 2007) is, to the best of the author's knowledge, the only attempt at producing a multi-objective PSO hybrid algorithm. Here again, further investigation is necessary.

Although research into these evolutionary hybrid algorithms is over a decade old, with several good approaches having been suggested, there is no clear consensus about which approach is best suited for any given application. More research in this direction is warranted to obtain further insights into the performance of these algorithms.

CONCLUSION

In the literature on evolutionary optimization, many effective approaches have been proposed to hybridize GAs with Nelder-Mead simplex. More recently, researchers have begun implementing similar ideas within PSO also. A few papers on multi-objective hybrid approaches have been published. However, a formal framework to categorize all these approaches has so far been lacking. This chapter surveys the various methods and proposes a way to organize them into four distinct categories.

KEY TERMS

Dominance: A relationship between solutions in a multi-objective optimization problem. A solution dominates another if and only if it is equal to the latter in all the objectives and better in at least one.

Evolutionary Algorithm: A class of probabilistic algorithms that are based upon biological metaphors such as Darwinian evolution, and widely used in optimization.

Exploration: A strategy that samples the fitness landscape extensively to obtain good regions.

Exploitation: A greedy strategy that seeks to improve one or more solutions to an optimization problem to take it to a maximum in its vicinity.

Fitness: A measure to determine the goodness of a solution to an optimization problem. When a single objective is to be maximized, the fitness is either equal to the objective or a monotonically increasing function of it.

Fitness Landscape: A representation of the search space of an optimization problem that brings out the differences in the fitness of the solutions, such that those with good fitness are “higher”. Optimal solutions are the maxima of the fitness landscape.

Generation: A term used in evolutionary algorithms that corresponds to an iteration of the outermost loop.

Local Search: A search algorithm to carry out exploitation.

Multi-Objective Optimization: An optimization problem involving more than a single objective function. In such a setting, it is not easy to discriminate between good and bad solutions, as a solution that is better than another in one objective may be poorer in another. Without any loss of generality, each objective function can be considered to be one involving maximization.

Population-Based Algorithm: An algorithm, which maintains an entire set of candidate solutions for an optimization problem.

Search Space: Set of all possible solutions for any given optimization problem, in which one can usually define a neighborhood of any solution.

Neural Control System for Autonomous Vehicles

Francisco García-Córdova

Polytechnic University of Cartagena (UPCT), Spain

Antonio Guerrero-González

Polytechnic University of Cartagena (UPCT), Spain

Fulgencio Marín-García

Polytechnic University of Cartagena (UPCT), Spain

INTRODUCTION

Neural networks have been used in a number of robotic applications (Das & Kar, 2006; Fierro & Lewis, 1998), including both manipulators and mobile robots. A typical approach is to use neural networks for nonlinear system modelling, including for instance the learning of forward and inverse models of a plant, noise cancellation, and other forms of nonlinear control (Fierro & Lewis, 1998).

An alternative approach is to solve a particular problem by designing a specialized neural network architecture and/or learning rule (Sutton & Barto, 1981). It is clear that biological brains, though exhibiting a certain degree of homogeneity, rely on many specialized circuits designed to solve particular problems.

We are interested in understanding how animals are able to solve complex problems such as learning to navigate in an unknown environment, with the aim of applying what is learned of biology to the control of robots (Chang & Gaudiano, 1998; Martínez-Marín, 2007; Montes-González, Santos-Reyes & Ríos-Figueroa, 2006).

In particular, this article presents a neural architecture that makes possible the integration of a kinematical adaptive neuro-controller for trajectory tracking and an obstacle avoidance adaptive neuro-controller for nonholonomic mobile robots. The kinematical adaptive neuro-controller is a real-time, unsupervised neural network that learns to control a nonholonomic mobile robot in a nonstationary environment, which is termed Self-Organization Direction Mapping Network (SODMN), and combines associative learning and Vector Associative Map (VAM) learning to generate transformations between spatial and velocity

coordinates (García-Córdova, Guerrero-González & García-Marín, 2007). The transformations are learned in an unsupervised training phase, during which the robot moves as a result of randomly selected wheel velocities. The obstacle avoidance adaptive neuro-controller is a neural network that learns to control avoidance behaviours in a mobile robot based on a form of animal learning known as operant conditioning. Learning, which requires no supervision, takes place as the robot moves around a cluttered environment with obstacles. The neural network requires no knowledge of the geometry of the robot or of the quality, number, or configuration of the robot's sensors. The efficacy of the proposed neural architecture is tested experimentally by a differentially driven mobile robot.

BACKGROUND

Several heuristic approaches based on neural networks (NNs) have been proposed for identification and adaptive control of nonlinear dynamic systems (Fierro & Lewis, 1998; Pardo-Ayala & Angulo-Bahón, 2007).

In wheeled mobile robots (WMR), the trajectory-tracking problem with exponential convergence has been solved theoretically using time-varying state feedback based on the backstepping technique in (Ping & Nijmeijer, 1997; Das & Kar, 2006). Dynamic feedback linearization has been used for trajectory tracking and posture stabilization of mobile robot systems in chained form (Oriolo, Luca & Vendittelli, 2002).

The study of autonomous behaviour has become an active research area in the field of robotics. Even the simplest organisms are capable of behavioural feats unimaginable for the most sophisticated machines. When

an animal has to operate in an unknown environment it must somehow learn to predict the consequences of its own actions. Biological organisms are a clear example that this sort of learning is possible in spite of what, from an engineering standpoint, seem to be insurmountable difficulties: noisy sensors, unknown kinematics and dynamics, nonstationary statistics, and so on. A related form of learning is known as operant conditioning (Grossberg, 1971). Chang and Gaudiano (1998) introduce a neural network for obstacle avoidance that is based on a model of classical and operant conditioning.

Psychologists have identified classical and operant conditioning as two primary forms of learning that enables animals to acquire the causal structure of their environment. In the classical conditioning paradigm, learning occurs by repeated association of a Conditioned Stimulus (CS), which normally has no particular significance for an animal, with an Unconditioned Stimulus (UCS), which has significance for an animal and always gives rise to an Unconditioned Response (UCR). The response that comes to be elicited by the CS after classical conditioning is known as the Conditioned Response (CR) (Grossberg & Levine, 1987). Hence, classical conditioning is the putative learning process that enables animals to recognize informative stimuli in the environment.

In the case of operant conditioning, an animal learns the consequences of its actions. More specifically, the animal learns to exhibit more frequently a behaviour that has led to reward in the past, and to exhibit less frequently a behaviour that led to punishment.

In the field of neural networks research, it is often suggested that neural networks based on associative learning laws can model the mechanisms of classical conditioning, while neural networks based on reinforcement learning laws can model the mechanisms of operant conditioning (Chang & Gaudiano, 1998).

The reinforcement learning is used to acquire navigation skills for autonomous vehicles, and updates both the vehicle model and optimal behaviour at the same time (Galindo, González & Fernández-Madriral, 2006; Lamiroux & Laumond, 2001; Galindo, Fernández-Madriral & González, 2007).

In this article, we propose a neurobiologically inspired neural architecture to show how an organism, in this case a robot, can learn without supervision to recognize simple stimuli in its environment and to associate them with different actions.

ARCHITECTURE OF THE NEURAL CONTROL SYSTEM

Figure 1(a) illustrates our proposed neural architecture. The trajectory tracking control without obstacles is implemented by the SODMN and a neural network of biological behaviour implements the avoidance behaviour of obstacles.

Self-Organization Direction Mapping Network (SODMN)

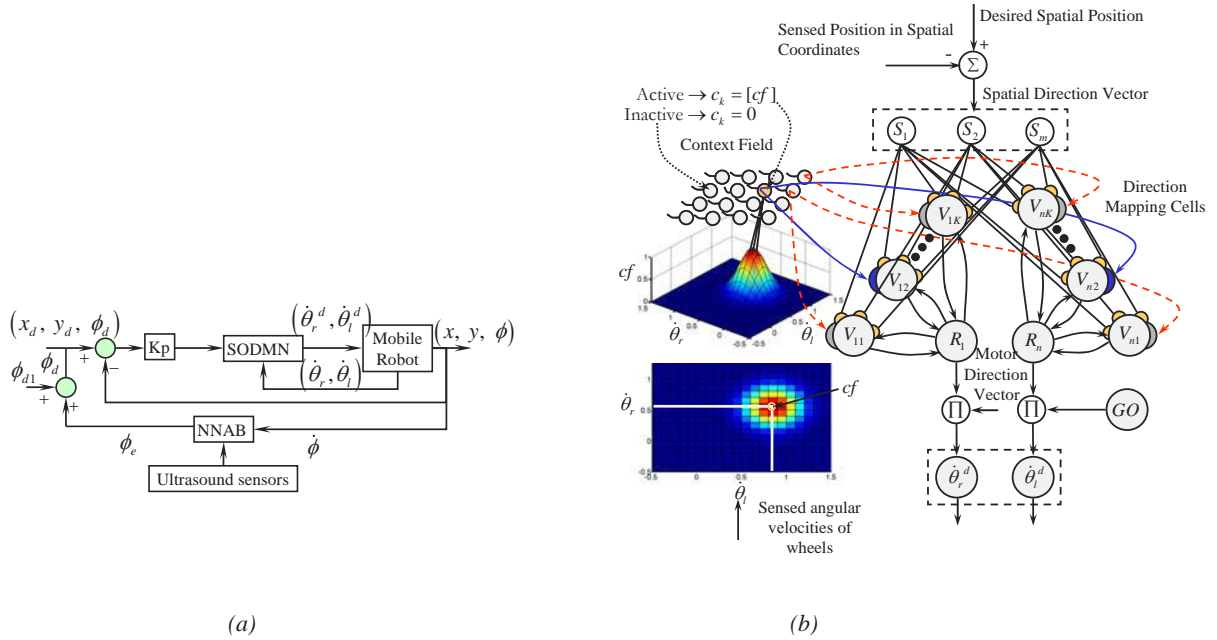

The transformation of spatial directions to wheels angular velocities is expressed like a linear mapping and is shown in Fig. 1(b). The spatial error is computed to get a spatial direction vector (DVs). The DVs is transformed by the *direction mapping network* elements V_{ik} to corresponding motor direction vector (DVm). On the other hand, a set of tonically active inhibitory cells, which receive broad-based inputs that determine the context of a motor action, was implemented as a context field. The context field selects the V_{ik} elements based on the wheels angular velocities configuration.

A speed-control GO signal acts as a non-specific multiplicative gate and controls the movement's overall speed. The GO signal is an input from a decision centre in the brain, and starts at zero before movement and then grows smoothly to a positive value as the movement develops. During the learning, the GO signal is inactive.

Activities of cells of the DVs and DVm are represented in the neural network by quantities (S_1, S_2, \dots, S_m) and (R_1, R_2, \dots, R_n) , respectively. The direction mapping is formed with a field of cells with activities V_{ik} . Each V_{ik} cell receives the complete set of spatial inputs $S_j, j = 1, \dots, m$, but connects to only one R_i cell. The direction mapping cells ($\mathbf{V} \in \mathbb{R}^{n \times k}$) compute a difference of activity between the spatial and motor direction vectors via feedback from DVm. During learning, this difference drives the adjustment of the weights. During performance, the difference drives DVm activity to the value encoded in the learned mapping.

A context field cell pauses when it recognizes a particular velocity state (i.e., a velocity configuration) on its inputs, and thereby disinhibits its target cells. The target cells (direction mapping cells) are completely shut off when their context cells are active (see Fig. 1(b)). Each context field cell projects to a set of

Figure 1. (a) Neural architecture for reactive and adaptive navigation of a mobile robot. (b) Self-organization direction mapping network for the trajectory tracking of a mobile robot.

direction mapping cells, one for each velocity vector component. Each velocity vector component has a set of direction mapping cells associated with it, one for each context. A cell is “off” for a compact region of the velocity space. It is assumed for simplicity that only one context field cell turns “off” at a time. The centre context field cell is “off” when the angular velocities are in the centre region of the velocity space. The “off” context cell enables a subset of direction mapping cells through the inhibition variable c_k , while “on” context cells disable the other subsets.

The learning is obtained by decreasing weights in proportion to the product of the presynaptic and post-synaptic activities (Gaudiano, & Grossberg, 1991). The training is done by generating random movements, and by using the resulting angular velocities and observed spatial velocities of the mobile robot as training vectors to the direction mapping network.

Neural Network for the Avoidance Behaviour (NNAB)

Grossberg proposed a model of classical and operant conditioning, which was designed to account for a

variety of behavioural data on learning in vertebrates (Grossberg, 1971; Grossberg & Levine, 1987). Our implementation is based in the Grossberg’s conditioning circuit, which follows closely that of Grossberg & Levine (1987) and Chang & Gaudiano (1998), and is shown in Figure 2.

In this model the sensory cues (both CSs and UCS) are stored in Short Term Memory (STM) within the population labelled S , which includes competitive interactions to ensure that the most salient cues are contrast enhanced and stored in STM while less salient cues are suppressed. The population S is modelled as a recurrent competitive field in simplified discrete-time version, which removes the inherent noise, efficiently normalizes and contrast-enhances from the ultrasound sensors activations. In the present model, the CS nodes correspond to activation from the robot’s ultrasound sensors. In the network I_i represents a sensor value which codes proximal objects with large values and distal objects with small values. The network requires no knowledge of the geometry of the mobile robot or the quality, number, or distribution of sensors over the robot’s body.

Fig. 2. Neural Network for the avoidance behaviour

The drive node D corresponds to the Reward/Punishment component of operant conditioning (an animal/robot learns the consequences of its own actions). Learning can only occur when the drive node is active. Activation of drive node D is determined by the weighted sum of all the CS inputs, plus the UCS input, which is presumed to have a large, fixed connection strength. The drive node D is active when the robot collides with an obstacle. Then the unconditioned stimulus (USC) in this case corresponds to a collision detected by the mobile robot. The activation of the drive node and of the sensory nodes converges upon the population of polyvalent cells P . Polyvalent cells require the convergence of two types of inputs in order to become active. In particular, each polyvalent cell receives input from only one sensory node, and all polyvalent cells also receive input from the drive node D .

Finally, the neurons (xm_j) represent the response conditioned or unconditioned and are thus connected to the motor system. The motor population consists of nodes (i.e., neurons) encoding desired angular velocities of avoidance. When driving the robot, activation is distributed as a Gaussian centred on the desired angular velocity of avoidance. The use of a Gaussian leads to smooth transitions in angular velocity even with few nodes.

The output of the angular velocity population is decomposed by SODMN into left and right wheel angular velocities. A gain term can be used to specify the maximum possible velocity. In NNAB the proximity sensors initially do not propagate activity to the motor population because the initial weights are

small or zero. The robot is trained by allowing it to make random movements in a cluttered environment. Whenever the robot collides with an obstacle during one of these movements (or comes very close to it), the nodes corresponding to the largest (closest) proximity sensor measurements just prior to the collision will be active. Activation of the drive node D allows two different kinds of learning to take place: the learning that couples sensory nodes (infrared or ultrasounds) with the drive node (the collision), and the learning of the angular velocity pattern that existed just before the collision.

The first type of learning follows an associative learning law with decay. The primary purpose of this learning scheme is to ensure that learning occurs only for those CS nodes that were active within some time window prior to the collision (UCS). The second type of learning, which is also of an associative type but inhibitory in nature, is used to map the sensor activations to the angular velocity map. By using an inhibitory learning law, the polyvalent cell corresponding to each sensory node learns to generate a pattern of inhibition that matches the activity profile active at the time of collision.

Once learning has occurred, the activation of the angular velocity map is given by two components (see Figure 3). An excitatory component, which is generated directly by the sensory system, reflects the angular velocity required to reach a given target in the absence of obstacles. The second, inhibitory component, generated by the conditioning model in response to sensed obstacles, moves the robot away from the obstacles

Figure 3. Positive Gaussian distribution represents the angular velocity without obstacle and negative distribution represents activation from the conditioning circuit. The summation represents the angular velocity that will be used to drive the mobile robot.

as a result of the activation of sensory signals in the conditioning circuit.

EXPERIMENTAL RESULTS

The proposed control algorithm is implemented on a mobile robot from the Polytechnic University of Cartagena (UPCT) named “CHAMAN”. The platform has two driving wheels (in the rear) mounted on the same axis and two passive supporting wheels (in front) of free orientation. The two driving wheels are independently driven by two DC-motors to achieve the motion and orientation.

High-level control algorithms (SODMN and NNAB) are written in VC++ and run with a sampling time of 10 ms on a remote server (a Pentium IV processor). The lower level control layer is in charge of the execution of the high-level velocity commands. It consists of a Texas Instruments TMS320C6701 Digital Signal Processor (DSP).

Figure 4 shows approach behaviours and the tracking of a trajectory by the mobile robot with respect to the reference trajectory.

Figure 5 illustrates the mobile robot’s performance in the presence of several obstacles. The mobile robot starts from the initial position labelled X and reaches a desired position. During the movements, whenever the

mobile robot is approaching an obstacle, the inhibitory profile from the conditioning circuit (NNAB) changes the selected angular velocity and makes the mobile robot turn away from the obstacle.

FUTURE TRENDS

The tendency of robots’ control systems is to come to understand and to imitate the way that biological systems learn and evolve to resolve complex problems in unknown environments. Simple animals (e.g.: crabs, insects, scorpions and other ones) are studied to formalize robust neural models for the robots’ locomotion system. In humans, decoded neural behaviors of neural activities of the cortical system tend to be applying to robotic prosthesis for the control of movement. Neural networks and other bio-mimetic techniques with an emphasis on navigation and control are used to operate in real-time with only minimal assumptions about the robots or the environment, and that can learn, if needed, with little or no external supervision.

In this article, the proposed neural control system can be applied for underwater applications. In this case, sonar sensors will replace ultrasound sensors. The proposed neural architecture learns to carry out a reactive and adaptive navigation nonstationary environments.

CONCLUSION

In this article, we have implemented a neural architecture for trajectory tracking and avoidance behaviours of mobile robot. A biologically inspired neural network for the spatial reaching tracking has been developed. This neural network is implemented as a kinematical adaptive neuro-controller. The SODMN uses a context field for learning the direction mapping between spatial and angular velocity coordinates. The performance of this neural network has been successfully demonstrated in experimental results with the trajectory tracking and reaching of a mobile robot. The avoidance behaviours of obstacles were implemented by a neural network that is based on a form of animal learning known as operant conditioning. A differentially driven mobile robot tested the efficacy of the proposed neural network for avoidance behaviours experimentally.

KEY TERMS

Artificial Neural Network: A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data; and are used in applications such as robotics, speech recognition, and signal processing or medical diagnosis.

Classical Conditioning: It is a form of associative learning that was first demonstrated by Ivan Pavlov. The typical procedure for inducing classical conditioning involves a type of learning in which a stimulus acquires the capacity to evoke a response that was originally evoked by another stimulus.

Conditioned Response (CR): If the conditioned stimulus and the unconditioned stimulus are repeatedly paired, eventually the two stimuli become associated and the organism begins to produce a behavioral response to the conditioned stimulus. Then, the conditioned response is the learned response to the previously neutral stimulus.

Conditioned Stimulus (CS): It is a previously neutral stimulus that, after becoming associated with the unconditioned stimulus, eventually comes to trigger a conditioned response. The neutral stimulus could be any event that does not result in an overt behavioral response from the organism under investigation.

Operant Conditioning: The term “Operant” refers to how an organism operates on the environment, and hence, operant conditioning comes from how we respond to what is presented to us in our environment. Then the operant conditioning is a form of associative learning through which an animal learns about the consequences of its behaviour.

Unconditioned Response (UR): It is the unlearned response that occurs naturally in response to the unconditioned stimulus.

Unconditioned Stimulus (UCS): Which is one that unconditionally, naturally, and automatically triggers an innate, often reflexive, response in the presence of significant stimulus. For example, when you smell one of your favourite foods, you may immediately feel very hungry. In this example, the smell of the food is the unconditioned stimulus.

Neural Network–Based Visual Data Mining for Cancer Data

INTRODUCTION

According to the World Health Organization (<http://www.who.int/cancer/en>), cancer is a leading cause of death worldwide. From a total of 58 million deaths in 2005, cancer accounts for 7.6 million (or 13%) of all deaths. The main types of cancer leading to overall cancer mortality are *i*) Lung (1.3 million deaths/year), *ii*) Stomach (almost 1 million deaths/year), *iii*) Liver (662,000 deaths/year), *iv*) Colon (655,000 deaths/year) and *v*) Breast (502,000 deaths/year). Among men the most frequent cancer types worldwide are (in order of number of global deaths): lung, stomach, liver, colorectal, oesophagus and prostate, while among women (in order of number of global deaths) they are: breast, lung, stomach, colorectal and cervical.

Technological advancements in recent years are enabling the collection of large amounts of cancer related data. In particular, in the field of Bioinformatics, high-throughput microarray gene experiments are possible, leading to an information explosion. This requires the development of data mining procedures that speed up the process of scientific discovery, and the in-depth understanding of the internal structure of the data. This is crucial for the non-trivial process of identifying valid, novel, potentially useful, and ultimately *understandable patterns* in data (Fayyad, Piatetsky-Shapiro & Smyth, 1996). Researchers need to *understand* their data rapidly and with greater ease. In general, objects under study are described in terms of collections of *heterogeneous* properties. It is typical for medical data to be composed of properties represented by nominal, ordinal or real-valued variables (scalar), as well as by others of a more complex nature, like images, time-series, etc. In addition, the information

comes with different degrees of precision, uncertainty and information completeness (missing data is quite common).

Classical data mining and analysis methods are sometimes difficult to use, the output of many procedures may be large and time consuming to analyze, and often their interpretation requires special expertise. Moreover, some methods are based on assumptions about the data which limit their application, specially for the purpose of exploration, comparison, hypothesis formation, etc, typical of the first stages of scientific investigation. This makes graphical representation directly appealing. Humans perceive most of the information through vision, in large quantities and at very high input rates. The human brain is extremely well qualified for the fast understanding of complex visual patterns, and still outperforms the computer. Several reasons make Virtual Reality (VR) a suitable paradigm: *i*) it is *flexible* (it allows the choice of different representation models to better suit human perception preferences), *ii*) allows *immersion* (the user can navigate inside the data, and interact with the objects in the world), *iii*) creates a *living* experience (the user is not merely a passive observer, but an actor in the world) and *iv*) VR is *broad and deep* (the user may see the VR world as a whole, and/or concentrate on specific details of the world). Of no less importance is the fact that in order to interact with a virtual world, only minimal skills are required.

Visualization techniques may be very useful for medical decision support in the oncology area. In this paper unsupervised neural networks are used for constructing VR spaces for visual data mining of gene expression cancer data. Three datasets are used in the paper, representative of three of the most important

types of cancer in modern medicine: liver, stomach and lung. The data sets are composed of samples from normal and tumor tissues, described in terms of tens of thousands of variables, which are the corresponding gene expression intensities measured in microarray experiments. Despite the very high dimensionality of the studied patterns, high quality visual representations in the form of structure-preserving VR spaces are obtained using SAMANN neural networks, which enables the differentiation of cancerous and noncancerous tissues. The same networks could be used as nonlinear feature generators in a preprocessing step for other data mining procedures.

NEURAL NETWORKS FOR THE CONSTRUCTION OF VIRTUAL REALITY SPACES

VR spaces for the visual representation of information systems (Pawlak, 1991) and relational structures were introduced in (Valdés, 2002a) (Valdés, 2003). A VR space is a tuple $\Omega = \langle O, G, B, R^m, g_0, l, g_r, b, r \rangle$, where O is a relational structure ($O = \langle O, \Gamma^V \rangle$), O is a finite set of objects, and Γ^V is a set of relations; G is a non-empty set of *geometries* representing the different objects and relations; B is a non-empty set of *behaviors* of the objects in the virtual world; $R^m \subseteq \mathbb{R}^m$ is a *metric space* of dimension m (Euclidean or not) which will be the actual VR geometric space. The other elements are mappings: $g_0 : O \rightarrow G$, $l : O \rightarrow R^m$, $g_r : \Gamma^V \rightarrow G$ and $b : O \rightarrow B$.

The typical *desiderata* for the visual representation of data and knowledge can be formulated in terms of minimizing information loss, maximizing structure preservation, maximizing class separability, or their combination, which leads to single or multi-objective optimization problems. In many cases, these concepts can be expressed deterministically using continuous functions with well defined partial derivatives. This is the realm of classical optimization where there is a plethora of methods with well known properties. In the case of heterogeneous information the situation is more complex and other techniques are required (Valdés, 2002b) (Valdés, 2004) (Valdés & Barton, 2005). In the unsupervised case, the function f mapping the original space to the VR (geometric) space R^m can be constructed as to maximize some metric/non-metric structure preservation criteria as is typical in multidimensional

scaling (Borg & Lingoes, 1987) or minimize some error measure of information loss (Sammon, 1969). A typical error measure is:

$$\text{Sammon Error} = \frac{1}{\sum_{i < j} \delta_{ij}} \frac{\sum_{i < j} (\delta_{ij} - \xi_{ij})^2}{\delta_{ij}}$$

where δ_{ij} is a dissimilarity measure between two objects i, j in the original space, and ξ_{ij} is another dissimilarity measure defined on objects i, j in the VR space (the images of i, j under f). Typical dissimilarity measures for δ_{ij} are the Euclidean distance or the dissimilarity based on Gower's similarity coefficient (Gower, 1971). The Euclidean distance is the usual measure for ξ_{ij} in the VR space.

Usually, the mappings f obtained using approaches of this kind are *implicit* because the images of the objects in the new space are computed directly. However, a functional representation of f is highly desirable, specially in cases where more samples are expected *a posteriori* and need to be placed within the space. With an implicit representation, the space has to be computed every time that a new sample is added to the set, whereas with an explicit representation, the mapping can be computed directly. As long as the incoming objects can be considered as belonging to the same population of samples used for constructing the mapping function, the space does not need to be recomputed. Neural networks are natural candidates for constructing explicit representations due to their general universal approximation property. If proper training methods are used, neural networks can learn structure preserving mappings of high dimensional samples into lower dimensional spaces suitable for visualization (2D, 3D). If visualization is not a requirement, spaces of smaller dimension than the original can be used as new features for noise reduction or other data mining methods. Such an example is the SAMANN network. This is a feedforward network and its architecture consists of an input layer with as many neurons as descriptor attributes, an output layer with as many neurons as the dimension of the VR space and one or more hidden layers. The classical way of training the SAMANN network is described in (Mao & Jain, 1995). It consists of a gradient descent method where the derivatives of the Sammon error are computed in a similar way to the classical backpropagation algorithm. Different from the backpropagation algorithm,

the training is unsupervised and the weights can only be updated after a pair of examples are presented to the network.

CANCER DATA SETS DESCRIPTION

Three microarray gene expression cancer databases were selected. They are representative of some of the leading causes of cancer death in the world and share the typical features of these kind of data: a small number of samples (in the order of tens), described in terms of a very large number of attributes (in the order of tens of thousands).

Liver Cancer Data

We used the same data as in (Lam, Wu, Vega, Miller, Spitsbergen, Tong, Zhan, Govindarajan, Lee, Mathavan, Murthy, Buhler, Liu & Gong, 2006), where zebrafish liver tumors were analyzed and compared with human liver tumors. The database (http://www.ncbi.nlm.nih.gov/projects/geo/gds/gds_browse.cgi?gds=2220) contains 20 samples (10 normal, 10 tumor), with 16,512 attributes. First, liver tumors in zebrafish were generated by treating them with carcinogens. Then, the expression profiles of zebrafish liver tumors were compared with those of zebrafish normal liver tissues using a Wilcoxon rank-sum test. As a result of this comparison, a zebrafish liver tumor differentially expressed gene set consisting of 2,315 gene features was obtained. This data set was used for comparison with human tumors. The results suggest that the molecular similarities between zebrafish and human liver tumors are greater than the molecular similarities between other types of tumors (stomach, lung and prostate).

Stomach Cancer Data

We used the same data as in (Hippo, Taniguchi, Tsutsumi, Machida, Chong, Fukayama, Kodama & Aburatani, 2002), where a study of genes that are differentially expressed in cancerous and noncancerous human gastric tissues was performed. The database (http://www.ncbi.nlm.nih.gov/projects/geo/gds/gds_browse.cgi?gds=1210) contains 30 samples (22 tumor, 8 normal) that were analyzed by oligonucleotide microarray, obtaining the expression profiles for 6,936 genes (7,129 attributes). Using the 6,272

genes that passed a prefilter procedure, cancerous and noncancerous tissues were successfully distinguished with a two-dimensional hierarchical clustering using Pearson's correlation. However, the clustering results used most of the genes on the array. To identify the genes that were differentially expressed between cancer and noncancerous tissues, a Mann-Whitney's U test was applied to the data. As a result of this analysis, 162 and 129 genes showed a higher expression in cancerous and noncancerous tissues, respectively. In addition, several genes associated with lymph node metastasis and histological classification (intestinal, diffuse) were identified.

Lung Cancer Data

We used the same data as in (Spira, Beane, Pinto-Plata, Kadar, Liu, Shah, Celli & Brody, 2004), where gene expressions were compared in for severely emphysematous lung tissue (from smokers at lung volume reduction surgery) and normal or mildly emphysematous lung tissue (from smokers undergoing resection of pulmonary nodules). The database (http://www.ncbi.nlm.nih.gov/projects/geo/gds/gds_browse.cgi?gds=737) contains 30 samples (18 severe emphysema, 12 mild or no emphysema), with 22,283 attributes. Genes with large detection P-values were filtered out, leading to a data set with 9,336 genes, that were used for subsequent analysis. Nine classification algorithms were used to identify a group of genes whose expression in the lung distinguished severe emphysema from mild or no emphysema. First, model selection was performed for every algorithm by leave-one-out cross-validation, and the gene list corresponding to the best model was saved. The genes reported by at least four classification algorithms (102 genes) were chosen for further analysis. With these genes, a two-dimensional hierarchical clustering using Pearson's correlation was performed that distinguished between severe emphysema and mild or no emphysema. Other genes were also identified that may be causally involved in the pathogenesis of the emphysema.

EXPERIMENTAL SETTINGS

Data Preprocessing

For stomach and lung data, each gene was scaled to mean zero and standard deviation one (original data

were not normalized). For liver data, no transformation was performed (original data were \log_2 ratios).

Model Training

For every data set, SAMANN networks were constructed to map the original data to a 3D VR space. The Euclidean distance was the dissimilarity measure used for both the original and the VR spaces. The activation functions used were sinusoidal for the first hidden layer and hyperbolic tangent for the rest. A collection of models was obtained by varying some of the network controlling parameters: number of units in the first hidden layer (two different values), weights ranges in the first hidden layer (three different values), learning rates (three different values), momentum (three different values), number of pairs presented to the network at every iteration (three different values), number of iterations (three different values) and random seeds (four different values), for a total of 1,944 SAMANN networks for every data set.

Computing Environment

All of the experiments were conducted on a Condor pool (<http://www.cs.wisc.edu/condor>) located at the Institute for Information Technology, National Research Council Canada.

RESULTS

For every data set, we constructed the histograms of the Sammon error for the obtained networks. All of the empirical distributions were positively skewed (with the mode on the lower error side), which is a good behavior. In addition, the general error ranges were small. In table 1 some statistics of the experiments are presented: minimum, maximum, mean and Standard

deviation for the best (i.e., with smallest Sammon error) 1,000 networks.

Clearly, it is impossible to represent a VR space on printed media (navigation, interaction, and world changes are all lost). Therefore, very simple geometries were used for objects and only snapshots of the virtual worlds are presented. Figures 1, 2 and 3 show the VR spaces corresponding to the best networks for the liver, stomach and lung cancer data sets respectively. Although the mapping was generated from an unsupervised perspective (i.e., without using the class labels), objects from different classes are differently represented in the VR space for comparison purposes. Transparent membranes wrap the corresponding classes, so that the degree of class overlapping can be easily seen. In addition, it allows to look for particular samples with ambiguous diagnostic decisions.

The low values of the Sammon error indicate that the spaces preserved most of the distance structure of the data, therefore, giving a good idea about the distribution in the original spaces. The three virtual spaces are clearly polarized with two distribution modes, each one corresponding to a different class. Note, however, that classes are more clearly differentiated for the liver and stomach data sets than for the lung data set, where a certain level of overlapping exists. The reason for this may be that mild and no emphysema were considered members of the same class (see above).

The advantage of using SAMANN networks is that, since the mapping f between the original and the virtual space is *explicit*, a new sample can be easily transformed and visualized in the virtual space. Since the distance between any two objects is an indication of their dissimilarity, the new point is more likely to belong to the same class of its nearest neighbors. In the same way, outliers can be readily identified, although they may result from the space deformation inevitably introduced by the dimensionality reduction.

Table 1. Statistics of the best 1,000 SAMANN networks obtained

| Data Set | Sammon Error | | | |
|----------------|--------------|----------|----------|----------|
| | Minimum | Maximum | Mean | Std.Dev. |
| Liver Cancer | 0.039905 | 0.055640 | 0.049857 | 0.003621 |
| Stomach Cancer | 0.062950 | 0.077452 | 0.072862 | 0.003346 |
| Luna Cancer | 0.079242 | 0.107842 | 0.094693 | 0.006978 |

CONCLUSION

High quality virtual reality spaces for visual data mining of typical examples of gene expression cancer data were obtained using unsupervised structure-preserving neural networks in a distributed computing data mining (grid) environment. These results show that a few nonlinear features can effectively capture the

similarity structure of the data and also provide a good differentiation between the cancer and normal classes. A similar study can be found in (Valdés, Romero & González, 2007).

However, in cases where the descriptor attributes are not directly related to class structure or where there are many noisy or irrelevant attributes the situation may not be as clear. In these cases, feature subset selection and other data mining procedures could be considered in a preprocessing stage.

KEY TERMS

Artificial Neural Networks: Interconnected group of simple units (neurons) that, as a function of the connections between the units and the parameters, can compute complex behaviors and find nonlinear relationships in data. They are used in applications such as robotics, signal processing, or medical diagnosis.

Backpropagation Algorithm: Algorithm to compute the gradient with respect to the weights, used for the training of some types of artificial neural networks. It was first described by P. Werbos in 1974, and further developed by D.E. Rumelhart, G.E. Hinton and R.J. Williams in 1986.

Condor: Specialized workload management system for computer-intensive jobs in a distributed computing environment, developed at the university of Wisconsin-Madison (<http://www.cs.wisc.edu/condor>). It provides a job queuing mechanism, resource

monitoring and management, scheduling policy, and priority scheme.

Data Mining: Nontrivial extraction of implicit, previously unknown and potentially useful information from data. Typically, analytical methods and tools are applied to data with the aim of identifying patterns, relationships or obtaining databases for tasks such as classification, prediction, estimation or clustering.

Gene Expression: Process by which the inheritable information which comprises a gene, such as the DNA sequence, is made manifest as a physical and biologically functional gene product, such as protein or RNA.

SAMANN Neural Networks: Unsupervised feedforward neural networks for data projection. The classical way of training SAMANN networks was described by J. Mao and A.K. Jain in 1995. It consists of a gradient descent method where the derivatives of the Sammon error are computed in a similar way to the backpropagation algorithm.

Sammon Error: Error function to maximize structure preservation in projected data. It is defined as

$$\frac{1}{\sum_{i < j} \delta_{ij}} \frac{\sum_{i < j} (\delta_{ij} - \xi_{ij})^2}{\delta_{ij}},$$

where δ_{ij} and ξ_{ij} are dissimilarity measures between two objects i, j in the original and projected space, respectively.

Virtual Reality: Technology which allows the user to interact with a computer-simulated environment. Most current virtual reality environments are mainly visual experiences, displayed either on a computer screen or through special stereoscopic displays. Some advanced haptic systems include tactile information.

Neural Network–Based Process Analysis in Sport

Juergen Perl

University of Mainz, Germany

INTRODUCTION

Processes in sport like motions or games are influenced by communication, interaction, adaptation, and spontaneous decisions. Therefore, on the one hand, those processes are often fuzzy and unpredictable and so have not extensively been dealt with, yet. On the other hand, most of those processes structurally are roughly determined by intention, rules, and context conditions and so can be classified by means of information patterns deduced from data models of the processes.

Self organizing neural networks of type Kohonen Feature Map (KFM) help for classifying information patterns – either by mapping whole processes to corresponding neurons (see Perl & Lames, 2000; McGarry & Perl, 2004) or by mapping process steps to neurons, which then can be connected by trajectories that can be taken as process patterns for further analyses (see examples below). In any case, the dimension of the original data (i.e. the number of contained attributes) is reduced to the dimension of the representing neuron (normally 2 or 3), which makes it much easier to deal with.

Additionally, extensions of the KFM-approach are introduced, which are able to flexibly adjust the net to dynamically changing training situations. Moreover, those extensions allow for simulating adaptation processes like learning or tactical behaviour.

Finally, a current project is introduced, where tactical processes in soccer are analysed under the aspect of simulation-based optimization.

BACKGROUND

A major problem in analysing complex processes in sport like motions or games often is the reduction of available data to useful information. Two examples shall make plain what the particular problems in sport are:

In Motor Analysis, a lot of data regarding positions, angles, speed, or acceleration of articulations can be recorded automatically by means of markers and high speed digital cameras. The problem is that those recorded data show a high degree of redundancy and inherent correlation: A leg consisting of thigh, lower leg, foot, and the articulations hip joint, knee, and ankle obviously has only a comparably small range of possible movements due to natural restrictions. Therefore the quota of characteristic motion data is comparably small as well. Classification can help for deducing that relevant information from recorded data by mapping them to representative types or patterns.

In Game Analysis, during the last about 5 years an increasing number of approaches have been developed which enable for automatic recording of position data. Based on the video time precision of 25 frames per second, 9.315.000 x-y-z-coordinate data from 22 players and the ball can be taken from a 90-minutes soccer game. Obviously, the amount of data has to be reduced and to be focused to the major tactical patterns of the teams. Similar to what coaches are doing, the collection of players' positions can be reduced to constellations of tactical groups which interact like super-players and therefore enable for a computer-aided game analysis based on pattern analysis.

As is demonstrated in the following, neural network-based pattern analysis can support the handling of those problems.

MAIN FOCUS OF THE CHAPTER

Artificial Neural Networks

Current developments in the fields of Soft Computing and/or Computational Intelligence demonstrate how information patterns can be taken from data collections by means of fuzziness, similarity and learning, which

the approach of Artificial Neural Networks gives an impressive example for. In particular self organizing neural networks of type KFM (Kohonen Feature Map) play an important role in aggregating input data to clusters or types by means of a self organized similarity analysis (Kohonen, 1995).

Net-Based Process Analysis

Processes can be mapped to attribute vectors – in a game, for example, by recording the positions of the players – which then can be learned by neurons. There is, of course, a certain loss of precision if replacing an attribute vector by a representing neuron, the entry of which is similar but normally not identical to that attribute vector. Nevertheless, there are two major advantages of the way a KFM maps input data to corresponding neurons:

1. The number of objects is dramatically reduced if using the representing neurons instead of the original attribute vectors: a 2-dimensional 20×20 -neuron-matrix contains 400 neurons, while a 10-dimensional vector space with only 10 different values per attribute already contains $10^{10} = 10.000.000.000$ vectors.
2. The dimension of input data is reduced to the dimension of the network (i.e. normally 2 or at most 3). This for example enables for mapping time-series of high-dimensional attribute vectors to trajectories of neurons that can easily be presented graphically.

There are three ways of gaining information from data by means of Artificial Neural Networks of KFM-type:

1. Neurons represent classes of similar data and so define types of information patterns.
2. Clusters of neurons represent time-static classes of similar information patterns and so build structures of information patterns.
3. Trajectories of neurons represent time-dynamic sequences of information patterns and so build 2-dimensional mappings of time-dependent processes. Moreover, trajectories themselves build patterns and therefore can be input to a network for classifying their similarities – which is extremely helpful not least in motor analysis or in game analysis.

There are a large number of successful applications that demonstrate how those neural networks can be used for that pattern analysis (see Perl & Dauscher, 2006).

Example “Gait Analysis”: Reduction of Redundancy and Dimensionality

In gait analysis, data from articulations like for example hip-joint, knee and ankle can automatically be recorded using markers and so build a time series of n -dimensional attribute vectors which can be trained to a net. The result is that each of those n -dimensional vectors is mapped to a 2-dimensional neuron of the net – i.e. the dimension is reduced from n to 2. Corresponding to the original time series the neurons can be connected by a

Figure 1. Two trajectories of the same gait process, using 20 attribute values (left) and 10 attribute values (right), respectively. The high degree of similarity suggests that the missing 10 values are redundant and can be neglected.

trajectory, which represents the original n-dimensional process through a 2-dimensional trajectory – therefore enabling for a much easier similarity analysis (Perl, 2004; Schöllhorn, 2004). Moreover, net-based analysis shows that, by avoiding redundancy, also the dimension of the original data can be reduced without losing relevant information (see Figure 1).

Example “Ergometer Rowing”: Inter- and Intra-Individual Process-Analysis

With the same approach that was used for gait analysis, the process of rowing was analyzed under the aspect of inter-individual similarity and intra-individual stability. Obviously, there is a great similarity on the set of all trajectories (see Figure 2).

However, the trajectories of rower A are perfectly similar to each other – demonstrating a high stability – while those of rower B are not as much. The experience with rowing pattern is that net-based analysis of rowing trajectories is very sensitive and helps for detecting even small instabilities which otherwise could not have been detected from video frames or original time series of data vectors (see Perl & Baca, 2003).

Example “Tactics in Games”: Constellation Analysis

In a more complex way, trajectories can improve the transparency of the tactical behaviour of players or even a team (net-based volleyball analysis: Jäger, Perl & Schöllhorn, 2007). A collection of player positions

– i.e. a constellation – can be represented by a vector of position coordinates, which then a net can be trained with. Figure 3 shows two exemplars of the same trained volleyball-net, with small squares representing activated constellations and marked areas representing major constellation types. Obviously, the teams represented by the left and the right net activate quite different types of constellation. Moreover, the moves between the constellations – i.e. the edges and/or trajectories – are quite different, too: The left team moves between the areas, while the right team more or less selects an area and then adjusts its constellation.

In a game like volleyball – i.e. with separated teams – it is comparably easy to deduce tactical ideas from those trajectory patterns. Some first result could be taken from handball too, where net-based analysis was helpful for detecting successful offence processes (net-based handball analysis: Pfeiffer & Perl, 2006; net-based soccer analysis: Lees et al., 2003; Leser, 2006). Based on those results, currently a project is run which deals with simulation-based tactics-optimisation in soccer. First results are encouraging. They were shown as video-representation at the famous Documenta-exhibition on fine arts, 2007 in Kassel/Germany.

Dynamic Extensions of KFM-Type Neural Networks

Self organizing maps of KFM-type are very helpful for analyzing dynamic processes. They fail, however, if learning or other process dynamics are parts of the processes to be trained. This is due to the fact that the

Figure 2. Trajectories of the rowing process of two rowers A and B, one stroke per graphic

Figure 3. Two examples of a net trained with constellations, where the marked squares represent frequent constellations and the marked areas represent major types of constellations.

learning procedure of a KFM is externally controlled, resulting in a network that works like a tool, without being able to change with or adapt to changing process types or contexts.

One successful approach that improves the dynamics of the learning process is that of the Dynamically Controlled Network (DyCoN: Perl, 2002 a/b), which is a KFM-derivate that is able to learn continuously. The idea is that each neuron contains an individual adaptive learning model based on the Performance Potential Metamodel (PerPot: Perl, 2002 a; learning strategies: Perl & Weber, 2004).

While DyCoN helps for analysing dynamic learning processes, a different type of neural network is necessary for simulating those learning processes – in order to eventually schedule and optimize those processes individually. One important point was to dynamically adapt the capacity of the network to the requirements of the learning process. This was done by integrating the concept of Growing Neural Gas (GNG: Fritzke, 1997), where, briefly spoken, the number and positions of neurons vary time-dependently with the changing information flow from training, this way adapting the network size and topology to the training amount and content. The result is the Dynamically Controlled Neural Gas (DyCoNG) the concept of which completes the combination of DyCoN and GNG by specific „quality neurons“ that reflect the information theoretical quality of information and therefore can measure the originality of a recorded activity (Perl et al., 2006). Based on the assumption that there is a strong correspondence

between the „quality“ of a neuron and the originality of the represented type of activity, the network’s reaction on an input-stimulus (i.e. generating a new connected/not connected quality neuron or not) indicates an evaluation of the originality of the corresponding activity. According to the two tasks „analysis of creativity learning“ and „simulation of creativity learning“, two major results could be obtained:

The DyCoN-model was used for analyzing the learning profiles, which were fed into as patterns and then recognized as members of clusters respectively types of learning behaviour. It was remarkable that the net could detect a number of significantly different types of learning behaviour – which in practice is useful for individually adjust the training to the athletes (Perl et al., 2006).

The DyCoNG-model was used for learning profile simulation, with the original activity- and rating-data as input and learning profiles as output. The learning profiles resulting from DyCoNG-training could also be separated into types which qualitatively correspond to those from DyCoN-analysis. This at least gives an idea of how to manage the above mentioned individual adaptation by means of net-based simulation.

In a first approach net-based originality analysis has successfully been used in case of handball: In a case study dealing with data from the Handball World Championship 2007 in Germany, offence activities of high originality could be detected with a remarkable high accordance to experts’ evaluation. Moreover, a degree of originality per team and game could be mea-

sured, resulting in team-specific originality profiles that characterize increasing and decreasing playing qualities during the tournament. Currently, a similar project is run with soccer, where in a first attempt the final of the World Championship 2006 is analyzed.

FUTURE TRENDS

The two major ideas for planned future work are to expand net-based simulation of originality to associative behaviour and to analyse the effects of virtually generated “creative” activities in simulated games.

Net-Based Simulation of Associative Behaviour

In a simplified way behaviour can be understood as recognizing the behavioural context like environment or situation followed by a context-oriented selection of a best fitting activity. In case of convergent behaviour this selection is more or less rule-based and determined. In case of divergent or creative behaviour the selection has a certain undetermined degree of freedom – i.e. spontaneous „jumps“ are possible from a first priority activity to associated ones. Mapped to neural networks, where activities can be thought to be connected to neurons, this means a „jump“ from the input-corresponding neuron to a different one – located either in a neighboured cluster or as an isolated quality neuron

Figure 4. Net with clusters (marked by slim lines), associative „jumps“ between clusters (bold dotted lines), and generated quality neuron (bold line)

(see Figure 4). Such an associative network could help for an improved simulation of „creative“ behaviour, based on a specific creativity potential that describes frequency, maximal distance, or neuron similarity of those associative jumps.

Improvement of Tactical Process Patterns

The idea of optimizing strategies by means of simulation was developed in the early 1980ies for games like tennis or badminton, where the player’s abilities and tactics in a simplified way can be characterized by two matrices: The action-depending transfer of situations can be measured by a transfer frequency matrix, while the situation-depending success of actions can be measured by an action success matrix. Based on those two matrices of both the players, a game can be simulated stochastically regarding its main process structures. Moreover, modifying the entries of the matrices – i.e. changing tactical aspects or technical skills – can help for improving tactical patterns by means of simulation.

Although soccer is much more complex than tennis or badminton, the same idea can be used if the complexity is reduced by introducing „super-players“ as we do in a current project: Groups of players, e.g. representing offence or defence, are combined to corresponding data objects, which are characterized by constellations of player positions. The interactions of the single players then are reduced to the interactions of the constellations or super-player, which makes it much easier to map the processes to networks for tactical analysis. The intended aim is to derive those characteristic matrices as well as information about creativity from the network in order to simulate games and improve tactical process patterns: As is indicated in Figure 5, a recorded original activity (white dot on the net) could be replaced by a apparently better or more creative one (white circle above the white dot), which in the simulation changes the regarding constellation and the resulting process and its success.

CONCLUSION

Net-based analysis of processes in sport is a difficult and challenging task because of the fuzziness and the indeterminism of athletes’ behaviour and interaction.

Figure 5. Steps of net-based analysis and simulation of games like soccer: Replacing players by positions and positions by constellations; analysing constellations by means of networks; simulative modification of tactical patterns; analysing simulated games in order to improve tactical and creative behaviour.

The result of about 30 years of work in this area is that a lot of problems could be solved methodically. The bottleneck, however, was the recording of data and the transfer to information. Meanwhile, data from biomechanical, physiological, and medical applications can be recorded automatically, and even in games like soccer automatic position recording has become possible. Therefore the problem has changed from “how to get data” to “how to transfer data to information”.

The presented net-based approaches show how this problem can be handled, opening new perspectives of transferring theoretical approaches to practical work.

KEY TERMS

Cluster: A collection of neurons is called a cluster, if they are similar and locally neighboured. Due to the topology preserving property of KfM-training classes of similar training vectors are mapped to clusters of neighboured neurons.

DyCoN: A DyCoN is a KFM-type network, where each neuron contains an individual PerPot-based self-control of its activation radius and learning rate. The DyCoN-concept enables for continuous learning and therefore supports continuous training and testing, training in phases and with generated data, on line-adaptation during tests and analyses, and flexible adaptation to new information patterns (Perl, 2002 a). (Note that DyCoN is used commercially. Therefore, technical details cannot be published but are under secrecy by DyCoS GmbH (www.dycos.net)).

DyCoNG: The concept of DyCoNG combines the concepts of DyCoN and GNG and completes it by dynamically generating “quality” neurons in order to represent relevant and rare information during the training process (Perl et al., 2006).

GNG: A GNG is network without a fixed neuron topology, which is able to generate new neurons on demand. Therefore a GNG is able to dynamically adapt its neuron structure to amount and structure of the trained information (Fritzke, 1997).

Information Pattern: An information pattern is a structure of information units like e.g. a vector or matrix of numbers, a stream of video frames, or a distribution of probabilities.

KFM: A KFM consists of a (normally: 2-dimensional) matrix of neurons, each of which contains a vector of attributes. Two neurons are called similar if the (Euclidian) distance of their attribute vectors is below a given threshold. Two neurons are called neighboured if they are next to each other regarding the given net topology (see Kohonen, 1995).

PerPot: PerPot is a model of dynamic adaptation, where an input flow feeds an internal strain potential as well as an internal response potentials, from which an output potential is fed by specifically delayed flows. Since the strain flow is negative and the response flow is positive, resulting in an oscillating stabilizing adaptation, the model is called antagonistic (Perl, 2002 a).

Test: In a test, an attribute vector is fed to the network to determine its type – i.e. the neuron it is corresponding to.

Training: During the training, attribute vectors are fed to the network and mapped to the corresponding neuron the entry of which is most similar to that of the attribute vector. After the training, the space of training attribute vectors is (more or less) completely represented by the neurons of the network – meaning that every training attribute vector belongs to a neuron the entry of which it is most similar to.

Type: The collection of attribute vectors that, after training, is represented by a neuron is called its type. Also the representing neuron can be called the type.

Neural Networks and Equilibria, Synchronization, and Time Lags

Daniela Danciu

University of Craiova, Romania

Vladimir Răsvan

University of Craiova, Romania

INTRODUCTION

All neural networks, both natural and artificial, are characterized by two kinds of dynamics. The first one is concerned with what we would call “learning dynamics”, in fact the sequential (discrete time) dynamics of the choice of synaptic weights. The second one is the intrinsic dynamics of the neural network viewed as a **dynamical system** after the weights have been established *via* learning. Regarding the second dynamics, the emergent computational capabilities of a **recurrent neural network** can be achieved provided it has **many equilibria**. The network task is achieved provided it approaches these equilibria. But the **dynamical system** has a dynamics induced *a posteriori* by the learning process that had established the synaptic weights. It is not compulsory that this *a posteriori* dynamics should have the required properties, hence they have to be checked separately.

The standard stability properties (Lyapunov, asymptotic and exponential stability) are defined for a single equilibrium. Their counterpart for **several equilibria** are: *mutability, global asymptotics, gradient behavior*. For the definitions of these general concepts the reader is sent to Gelig *et. al.*, (1978), Leonov *et. al.*, (1992).

In the last decades, the number of **recurrent neural networks**’ applications increased, they being designed for classification, identification and complex image, visual and spatio-temporal processing in fields as engineering, chemistry, biology and medicine (see, for instance: Fortuna *et. al.*, 2001; Fink, 2004; Atencia *et. al.*, 2004; Iwatori *et. al.*, 2005; Maurer *et. al.*, 2005; Guirguis & Ghoneimy, 2007). All these applications are mainly based on the existence of **several equilibria** for such networks, requiring them the “good behavior” properties above discussed.

Another aspect of the qualitative analysis is the so-called **synchronization** problem, when an external

stimulus, in most cases periodic or almost periodic has to be tracked (Gelig, 1982; Danciu, 2002). This problem is, from the mathematical point of view, nothing more but existence, uniqueness and global stability of forced oscillations.

In the last decades the neural networks dynamics models have been modified once more by introducing the transmission **delays**. The standard model of a Hopfield-type network with delay as considered in (Gopalsamy & He, 1994) is

$$\frac{du_i}{dt} = -a_i u_i(t) + \sum_{j=1}^n w_{ij} g_j(u_j(t - \tau_{ij})) + I_i \quad i = \overline{1, n} \quad (1)$$

The present paper aims to a general presentation, with both research and educational purposes, of the three topics mentioned previously.

BACKGROUND

Dynamical systems with **several equilibria** occur in such fields of science and technology as electrical machines, chemical reactions, economics, biology and, last but not least, neural networks.

For systems with **several equilibria** the usual local concepts of stability are not sufficient for an adequate description. The so-called “global phase portrait” may contain both stable and unstable equilibria: each of them may be characterized separately since stability is a local concept dealing with a specific trajectory. But global concepts are also required for a better system description and this is particularly true for the case of the neural networks. Indeed, the neural networks may be viewed as interconnections of simple computing elements whose computational capability is increased by interconnection (“emergent collective capacities”

– to cite Hopfield). This is due to the nonlinear characteristics leading to the existence of several stable equilibria. The network achieves its computing goal if no self-sustained oscillations are present and it always achieves some steady-state (equilibrium) among a finite (while large) number of such states.

This behavior is most suitably described by the concepts arising from the papers of Kalman (1957) and Moser (1967). The last of them relies on the following remark concerning the rather general nonlinear autonomous system

$$\dot{x} = -f(x), \quad x \in \mathbb{R}^n \quad (2)$$

where $f(x) = \text{grad } G(x)$ and $G : \mathbb{R}^n \rightarrow \mathbb{R}$ is such that the number of its critical points is finite and is radially unbounded i.e. $\lim_{|x| \rightarrow \infty} G(x) = \infty$. Under these assumptions any solution of (2) approaches asymptotically one of the equilibria (which is also a critical point of G – where its gradient, i.e. f vanishes). Obviously the best limit behavior of a neural network would be like this – naturally called **gradient like behavior**. Nevertheless there are other properties that are also important while weaker; in the following we shall discuss some of them.

The mathematical object will be in the following the system of ordinary differential equations

$$\dot{x} = f(x, t) \quad (3)$$

and we shall first define some basic notions.

Definition 1 a) Any constant solution of (3) is called **equilibrium**; the set of equilibria E is called **stationary set**. b) A solution of (3) is called **convergent** if it approaches asymptotically some equilibrium:

$$\lim_{t \rightarrow \infty} x(t) = c \in E \quad (4)$$

A solution is called **quasi-convergent** if it approaches asymptotically the stationary set:

$$\lim_{t \rightarrow \infty} d(x(t), E) = 0, \quad (5)$$

with $d(z, M)$ being the distance (in the usual sense) from the point z to the set M .

c) System (3) is called **monostable (strictly mutable)** if every bounded solution is convergent (in the above

sense); it is called **quasi-monostable** if every bounded solution is quasi-convergent.

d) System (3) is called **gradient-like** if every solution is convergent; it is called **quasi-gradient-like (has global asymptotics)** if every solution is quasi-convergent.

Remark that *convergence* is a solution property while *monostability* and *gradient* property are associated to systems. For autonomous (time invariant) systems of the form (2) the following Lyapunov type results are available.

Lemma 1 Consider system (2) and assume existence of a continuous function $V : \mathbb{R}^n \rightarrow \mathbb{R}$ that is nonincreasing along any of its solutions. If, additionally, a bounded on \mathbb{R}^+ solution $x(t)$ for which there exists some $\tau > 0$ such that $V(x(\tau)) = V(x(0))$ is an equilibrium, then the system is quasi-monostable.

Lemma 2 If the assumptions of Lemma 1 hold and, additionally, $V(x)$ is radially unbounded then system (2) is quasi-gradient like.

Lemma 3 If the assumptions of Lemma 2 hold and the set E is discrete (i.e. it consists of isolated points only) then system (2) is gradient-like.

DYNAMICS ISSUES OF RECURRENT NEURAL NETWORKS

Neural Networks as Systems with Several Equilibria

It has been already mentioned that the emergent computational capacities of the neural networks are ensured by: a) nonlinear behavior of the neural cells; b) their connectivity. These two properties define the neural networks as **dynamical systems with many equilibria** whose performance depends on the (high) number of these equilibria and on the **gradient like property** of the network.

On the other hand, the standard **recurrent neural networks** (Bidirectional Associative Memory (Kosko, 1988), Hopfield (1982), cellular (Chua & Yang, 1988), Cohen-Grossberg (1983)), which contain internal feedback loops - having thus the propensity for instability, possess some “natural”, i.e. associated in a natural way,

Lyapunov function allowing to obtain the required qualitative properties (Răşvan, 1998).

One of the most general models of neural networks that has a natural Lyapunov function is the Cohen-Grossberg model described by

$$\dot{x}_i = a_i(x_i) \left[b_i(x_i) - \sum_{j=1}^n c_{ij} d_j(x_j) \right], \quad i = \overline{1, n}, \quad (6)$$

with $c_{ij} = c_{ji}$; this model may be written as

$$\dot{x} = -A(x) \text{grad} V(x) \quad (7)$$

where $A(x)$ is a diagonal matrix with the entries

$$A_{ij}(x) = \frac{a_i(x_i)}{d'_i(x_i)} \delta_{ij} \quad (8)$$

and $V : \mathbb{R}^n \rightarrow \mathbb{R}$ is defined by

$$V(x) = \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n c_{ij} d_i(x_i) d_j(x_j) - \sum_{i=1}^n \int_0^{x_i} b_i(\lambda) d'_i(\lambda) d\lambda \quad (9)$$

The presence of $A(x)$ makes system (7) a *pseudo-gradient system* – compare to (2).

The properties of the associated **Lyapunov function** (9) will give sufficient conditions in order to obtain the required qualitative behaviors for the system. The derivative function of (9) is:

$$W(x) = -\sum_{i=1}^n a_i(x_i) d'_i(x_i) \left[b_i(x_i) - \sum_{j=1}^n c_{ij} d_j(x_j) \right]^2 \leq 0 \quad (10)$$

One can see that the inequality (10) holds provided $a_i(\lambda) > 0$ and $d_i(\lambda)$ are monotone nondecreasing. If additionally $d_i(\lambda)$ are strictly increasing, then the set where $W = 0$ consists of equilibria only. The system results *quasi-gradient like* i.e. every solution approaches asymptotically the stationary set.

Consider now a model of artificial neural network implemented by electrical circuits:

$$R_i C_i \frac{dv_i}{dt} = -v_i + \sum_{j=1}^n \frac{R_i}{R_{ij}} (\varphi_j(v_j) - v_j) + R_i I_i \quad (11)$$

with $\varphi_j(\cdot)$ being sigmoidal. Since sigmoidal functions

are subject to sector restrictions and global Lipschitz inequalities, it was only natural to try to improve the stability conditions using the **Lyapunov functions** suggested by the Popov frequency domain inequalities and the Yakubovich-Kalman-Popov lemma. For instance, in (Danciu & Răşvan, 2000) there was considered a rather general system with several sector restricted nonlinearities and the Lyapunov function was constructed in a rational way starting from an improved frequency domain stability inequality of Popov type with PI multiplier.

In the case of (11) this rather involved approach gives a **gradient like behavior** provided the symmetry condition $R_{ij} = R_{ji}$ is observed.

Time Delays in Neural Networks

We shall consider here the model (1). Since we do not dispose (yet) in the time delay case of an instrument like the Lyapunov like lemmas given in BACKGROUND, we have to restrict ourselves to the analysis of the stability of a particular equilibrium.

If $\bar{u}_i, i = 1, \dots, n$ is some equilibrium of (1) and if the deviations $z_i = u_i - \bar{u}_i$ are considered, the system in deviations is obtained

$$\frac{dz_i}{dt} = -a_i z_i(t) - \sum_{j=1}^n w_{ij} \varphi_j(z_j(t - \tau_{ij})), \quad i = \overline{1, n} \quad (12)$$

with $\varphi_j(z_j) = g_j(\bar{u}_j) - g_j(\bar{u}_j + z_j)$. As known, if $g_j : \mathbb{R} \mapsto \mathbb{R}$ satisfy the usual sigmoid conditions i.e. $g_j(0) = 0$, monotonically increasing and globally Lipschitz - that is

$$0 \leq \frac{g_j(\sigma_1) - g_j(\sigma_2)}{\sigma_1 - \sigma_2} \leq L_j, \quad \forall \sigma_1 \neq \sigma_2, \quad (13)$$

then φ_j defined above are such. With the usual notations of the field, let $z_i(\cdot) = z_i(t + \cdot)$ denote the state of (12) at t ; the state space will be considered $\mathcal{C}(-r, 0; \mathbb{R}^n)$ with $r = \max_{i,j} \tau_{ij}$, the space of continuous \mathbb{R}^n -valued mappings defined on $[-r, 0]$ with the usual norm of the uniform convergence. One considers the Lyapunov-Krasovskii functional (the analogue of the **Lyapunov function** of the delayless case) suggested by (Nishimura & Kitamura, 1969), $V : \mathcal{C} \mapsto \mathbb{R}_+$ as

$$I(X_c) = \sum_{o_i \in X} \sum_{o_j \in X, j > i} m_{i/c}.$$

$$\left[\lambda_i \int_0^{z_i(0)} \varphi_i(\theta) d\theta + \sum_{j=1}^n \int_{-\tau_{ij}}^0 (\rho_{ij} z_j^2(\theta) + \delta_{ij} \varphi_j^2(z_j(\theta))) d\theta \right] \quad (14)$$

with $\pi_i \geq 0$, $\lambda_i \geq 0$, $\rho_{ij} \geq 0$, $\delta_{ij} \geq 0$ some free parameters. Considering this functional along the solutions of (12) and differentiating it with respect to t we may find the so-called derivative functional $W : \mathcal{C} \mapsto \mathbb{R}$ as below

$$\begin{aligned} W(z) = & \sum_{i=1}^n \left[-a_i \pi_i z_i^2(0) - \lambda_i a_i \varphi_i(z_i(0)) z_i(0) - \right. \\ & \left. - [\pi_i z_i(0) + \lambda_i \varphi_i(z_i(0))] \sum_{j=1}^n w_{ij} \varphi_j(z_j(-\tau_{ij})) \right] + \\ & + \sum_{i=1}^n \sum_{j=1}^n [\rho_{ij} z_j^2(0) + \delta_{ij} \varphi_j^2(z_j(0)) - \rho_{ij} z_j^2(-\tau_{ij}) - \delta_{ij} \varphi_j^2(z_j(-\tau_{ij}))] \end{aligned} \quad (15)$$

The problem of the sign for W gives the following choice of the free parameters in (14) (Danciu & Răsvan, 2007):

$$\begin{aligned} \lambda_i > 0, \quad \sigma_i = a_i^2 - \left(\sum_{j=1}^m \frac{c_{ij}^2}{\delta_{ji}} \right) \sum_{j=1}^m (\rho_{ji} + \delta_{ji}) > 0 \\ 2 \left(\sum_{j=1}^m \frac{c_{ij}^2}{\delta_{ji}} \right)^{-1} (a_i - \sqrt{\sigma_i}) < \pi_i < 2 \left(\sum_{j=1}^m \frac{c_{ij}^2}{\delta_{ji}} \right)^{-1} (a_i + \sqrt{\sigma_i}) \end{aligned} \quad (16)$$

The application of the standard stability theorems for time delay systems (Hale & Verduyn Lunel, 1993) will give asymptotic stability of the equilibrium $z = 0$ ($u = \bar{u}$). The mathematical result reads as follows

Theorem 3: Consider system (12) with $a_i > 0$ and w_{ij} such that it is possible to choose $\rho_{ij} > 0$ and $\delta_{ij} > 0$ in order to satisfy $\sigma_i > 0$ with σ_i defined in (16). Then the equilibrium is globally asymptotically stable.

Synchronization Problems

From this point of view the *qualitative behavior* of the network is nothing more but behavior under the

time varying stimuli. This is particularly true for the modeling of rhythmic activities in the nervous system (Kopell, 2000) or the *synchronization* of the oscillatory responses (König & Schillen, 1991). Both rhythmicity and synchronization suggest some recurrence and this implies coefficients and stimuli being periodic or almost periodic. The model with time varying stimulus has the form

$$\frac{du_i}{dt} = -a_i u_i(t) - \sum_{j=1}^n w_{ij} f_j(u_j(t - \tau_{ij})) + c_i(t), \quad i = \overline{1, n} \quad (17)$$

under the same assumptions as previously, with the functions $f_i : \mathbb{R} \mapsto [-1, 1]$ being sigmoidal and therefore, globally Lipschitz. The forcing stimuli $c_i(t)$ are periodic or almost periodic and the *main mathematical problem* is to find conditions on the systems to ensure existence and exponential stability of a unique global (i.e. defined on f_i) solution which has the features of a limit regime, i.e. not defined by initial conditions and of the same type as the stimulus - periodic or almost periodic respectively. This is an “almost linear behavior” for reasons that are obvious. The approach to be taken in this problem is to obtain some estimates of the system’s solutions, which finally give information about system’s convergence and ultimate boundedness. Next we have to apply a fixed-point theorem and we use the theorems of Halanay (Halanay, 1967) on invariant manifolds for flows on Banach spaces (see (Danciu, 2002) for details and simulation results).

We give below a theorem based on the application of the Lyapunov functional (14) but restricted to be only quadratic in the state variables ($\lambda_i = 0$, $\delta_{ij} = 0$),

$$V(u) = \sum_{i=1}^n \left[\frac{1}{2} \pi_i u_i^2(0) + \sum_{j=1}^n \rho_{ij} \int_{-\tau_{ij}}^0 u_j^2(\theta) d\theta \right] \quad (18)$$

with $\pi_i > 0$, $\rho_{ij} > 0$, $i, j = \overline{1, n}$. We may state

Theorem 2 Assume that $a_i > 0$, $L_i > 0$ and w_{ij} are such that the derivative functional corresponding to $c_i(t) \equiv 0$ in (17) namely

$$W(u) = \sum_{i=1}^n \left[-a_i \pi_i u_i^2(0) - \pi_i u_i(0) \sum_{j=1}^n w_{ij} f_j(u_j(-\tau_{ij})) \right] + \sum_{i=1}^n \sum_{j=1}^n \rho_{ij} [u_j^2(0) - u_j^2(-\tau_{ij})]$$

(19)

is negative definite with a quadratic upper bound. Then the system (17) has a unique global solution $\bar{u}_i(t)$, $i = \overline{1, n}$ which is bounded on \mathbb{R} and exponentially stable. Moreover, this solution is periodic or almost periodic according to the character of $c_i(t)$ - periodic or almost periodic respectively.

FUTURE TRENDS

Supposing the field of AI has its own dynamics, the neural networks and their structures will evolve in order to improve the imitative behavior i.e. more of the “natural” intelligence will be transferred to AI. Consequently, science and technology will deal with new structures of various physical natures having **multiple equilibria**. At least the following qualitative behaviors will remain under study: stability-like properties (dichotomy, **gradient behavior** a.s.o.), **synchronization** (forced oscillations, almost linear behavior, chaos control) and complex dynamics (including chaotic behavior).

CONCLUSIONS

Our experience on neural networks dynamics shows that the most important study is to obtain conditions for gradient or quasi-gradient like behavior. Besides the comparison method of (Popov, 1979) which requires relaxation of the condition of the identical dynamics of all neurons, the most popular tool remains the Lyapunov method.

If the Lyapunov like lemmas given in BACKGROUND would be available in the time delay case, then improved Lyapunov functionals remaining constant on the set of equilibria could ensure a gradient like behavior.

KEY TERMS

Asymptotic Stability: The solution $\bar{x}(t)$ of (3) is called *asymptotically stable* if it is Lyapunov stable (see below) and, moreover, there exists $\delta_0 > 0$ such that if $|x_0 - \bar{x}(t_0)| < \delta_0$ then $\lim_{t \rightarrow \infty} |x(t; t_0, x_0) - \bar{x}(t)| = 0$.

Fixed Point Theorem: If $f(x)$ is some function of real variable with real values, the values such that $f(x) = x$ are called the *fixed points* of the mapping. In general, if $f : \mathbf{X} \mapsto \mathbf{X}$ is a mapping from the metric space \mathbf{X} into itself, the fixed points of this mapping are defined as above. A *fixed point theorem* is a theorem showing under which conditions some mapping has a fixed point in the corresponding metric space.

Frequency Domain Stability Inequality of Popov: Consider a feedback structure containing a linear dynamical block with the transfer function $H(s)$ and a nonlinear function - subject to the sector condition $0 < \phi(\sigma)\sigma < k\sigma^2$. The *Popov inequality* ensures absolute stability i.e. global asymptotic stability of the zero equilibrium for all nonlinear functions satisfying the above inequality and reads as follows: there exists some β such that

$$\frac{1}{k} + \Re(1 + j\omega\beta)H(j\omega) > 0, \quad \forall \omega \in \mathbb{R}$$

Global Stability: An equilibrium is *global (asymptotically) stable* if it is the unique equilibrium of the dynamical system and the property holds globally (its domain of attraction is the entire state space).

Lyapunov Function: State scalar function defined on the state space of a system in order to obtain some qualitative properties - stability of equilibria, oscillatory

behavior etc. - using a single function instead of several i.e. system's state trajectories. A Lyapunov function is usually positive definite and, along system's trajectories, is at least nonincreasing. The definite sign condition may also be relaxed for the generalized Lyapunov functions in the LaSalle sense. The basic physical model for the Lyapunov function is system's energy - a state function that is nonincreasing along the state trajectory being at the same time positive definite. The strength of the Lyapunov function is exactly its independence of the physical concepts since writing down the stored energy of a system is not an easy job except possibly such standard cases as mechanical systems or electrical circuits. The energy like concepts may be nevertheless inspiring when "guessing" a Lyapunov function. In the infinite dimensional cases e.g. time delay or propagation systems, the Lyapunov function is replaced by a *Lyapunov functional* defined on the infinite dimensional state space.

Oscillations (Self-Sustained and Forced): Type of steady state behavior when the state trajectories, while remaining bounded, never reach an equilibrium but their deviations from this equilibrium keep sign changing. Usually an oscillation is viewed as having some recurrent properties, being either periodic or almost periodic. When the system is autonomous i.e. free of external oscillatory signals while nevertheless displaying an oscillatory behavior which is sustained by non-oscillatory internal factors of the system, it is said that this system displays *self-sustained oscillations* (the term belongs to Mandelstamm and Andronov). When the system is non-autonomous and subject to external oscillatory signals (*stimuli*), the limit regime that occurs is called *forced oscillation*.

Phase Portrait: Term borrowed from the Poincaré theory of the phase (space) plane where this portrait is better defined. Its extension to higher order systems is mainly informal, based on geometric arguments. By *phase portrait* it is understood the total of state trajectories as limit regimes (equilibria, recurrent motions, limit sets) and standard trajectories e.g. defined by initial conditions.

Recurrent Neural Network (RNN): Neural networks which display feedback interconnections among their units (neurons). Due to these cyclic connections RNNs are nonlinear dynamical systems with very rich spatial and temporal behaviors: stable and unstable fixed points, limit cycles and chaotic behavior. These behaviors make them suitable for modeling certain cognitive functions such as associative memory, unsupervised learning, self-organizing maps and temporal reasoning.

Synchronization: Interaction phenomenon among coupled subsystems of a system resulting in some ordering of their evolution. Its maximal stage is the complete synchronization of the subsystems' periods resulting in a periodic evolution of the state of the entire system. When a system is externally forced by an oscillatory signal, synchronization means a limit regime of the entire state, which has the same waveform as the forcing signal (periodic with the same period if the forcing signal is periodic or almost periodic if the forcing signal is such).

Stability: Qualitative property of the solution of a system with the significance of the limitation of the perturbations effect on the considered solution viewed as basic. Among all kinds of stability (bounded input/bounded output, Lagrange stability, Birkhoff stability, input-to-state stability) the stability in the sense of Lyapunov - with respect to the initial conditions, viewed as incorporating the effect of short-period perturbations - is the most widely used; it means that sufficiently small deviations in the initial condition (state) will result in arbitrarily small deviations in the current state at all following moments. Rigorously, the basic solution $\bar{x}(t)$ of (3) is called *stable in the sense of Lyapunov* if, for any $\varepsilon > 0$ arbitrarily small and any $t_0 \in \mathbb{R}$ there exists some $\delta(\varepsilon, t_0) > 0$ sufficiently small such that if $|x_0 - \bar{x}(t_0)| < \delta(\varepsilon, t_0)$, then $|x(t; t_0, x_0) - \bar{x}(t)| < \varepsilon$ for all $t > t_0$. If in the above definition δ is independent of the initial moment t_0 the stability is called uniform; from the point of view of the practice, this is the more important stability notion of stability. It is also a necessary condition for uniform asymptotic stability (see above).

Neural Networks and HOS for Power Quality Evaluation

Juan J. González De la Rosa

Universities of Cádiz-Córdoba, Spain

Carlos G. Puntonet

University of Granada, Spain

A. Moreno-Muñoz

Universities of Cádiz-Córdoba, Spain

INTRODUCTION

Power quality (PQ) *event* detection and classification is gaining importance due to worldwide use of delicate electronic devices. Things like lightning, large switching loads, non-linear load stresses, inadequate or incorrect wiring and grounding or accidents involving electric lines, can create problems to sensitive equipment, if it is designed to operate within narrow voltage limits, or if it does not incorporate the capability of filtering fluctuations in the electrical supply (Gerek et. al., 2006; Moreno et. al., 2006).

The solution for a PQ problem implies the acquisition and *monitoring* of long data records from the energy distribution system, along with an automated detection and classification strategy which allows identify the cause of these voltage anomalies. Signal processing tools have been widely used for this purpose, and are mainly based in spectral analysis and wavelet transforms. These *second-order* methods, the most familiar to the scientific community, are based on the independence of the spectral components and evolution of the spectrum in the time domain. Other tools are threshold-based algorithms, linear classifiers and Bayesian networks. The goal of the signal processing analysis is to get a feature vector from the data record under study, which constitute the input to the computational intelligence modulus, which has the task of classification. Some recent works bring a different strategy, based in higher-order *statistics* (HOS), in dealing with the analysis of *transients* within PQ analysis (Gerek et. al., 2006; Moreno et. al., 2006) and other fields of Science (De la Rosa et. al., 2004, 2005, 2007).

Without perturbation, the 50-Hz of the voltage *waveform* exhibits a *Gaussian* behaviour. Deviations from Gaussianity can be detected and characterized via HOS. Non-Gaussian processes need third and fourth order statistical characterization in order to be recognized. In order words, *second-order* moments and *cumulants* could be not capable of differentiate non-*Gaussian events*. The situation described matches the problem of differentiating between a transient of long duration named fault (within a signal period), and a short duration transient (25 per cent of a cycle). This one could also bring the 50-Hz voltage to zero instantly and, generally affects the sinusoid dramatically. By the contrary, the long-duration transient could be considered as a modulating signal (the 50-Hz signal is the carrier). These *transients* are intrinsically non-stationary, so it is necessary a battery of observations (sample registers) to obtain a reliable characterization.

The main contribution of this work consists of the application of higher-order central cumulants to characterize PQ *events*, along with the use of a competitive layer as the classification tool. Results reveal that two different clusters, associated to both types of *transients*, can be recognized in the 2D graph. The successful results convey the idea that the physical underlying processes associated to the analyzed *transients*, generate different types of deviations from the typical effects that the noise cause in the 50-Hz sinusoid voltage *waveform*.

The paper is organized as follows: Section on higher-order cumulants summarizes the main equations of the cumulants used in the paper. Then, we recall the competitive layer's foundations, along with the *Kohonen* learning rule. The experience is described then, and the conclusions are drawn.

HIGHER-ORDER CUMULANTS

High-order *statistics*, known as *cumulants*, are used to infer new properties about the data of *non-Gaussian* processes (Mendel, 1991; Nikias & Mendel, 2003). The relationship among the cumulants of r stochastic signals, $\{x_i\}_{i \in [1,r]}$, and their moments of order p , $p \leq r$, can be calculated by using the *Leonov-Shiryayev* formula (Nandi, 1999; Nikias & Mendel, 2003). For an r th-order stationary random process $\{x(t)\}$, the r th-order cumulant is defined as the joint r th-order cumulant of the random variables $x(t)$, $x(t+\tau_1)$, ..., $x(t+\tau_{r-1})$,

$$C_{r,x}(\tau_1, \tau_2, \dots, \tau_r) = \text{Cum}[x(t), x(t+\tau_1), \dots, x(t+\tau_r)]. \quad (1)$$

Considering $\tau_1 = \tau_2 = \tau_3 = 0$ in Eq. (1), we have some particular cases:

$$\tau_{2,x} = E\{x^2(t)\} = C_{2,x}(0), \quad (2a)$$

$$\tau_{3,x} = E\{x^3(t)\} = C_{3,x}(0,0), \quad (2b)$$

$$\tau_{4,x} = E\{x^4(t)\} - 3(\tau_{2,x})^2 = C_{4,x}(0,0,0). \quad (2c)$$

Eqs. (2) are measurements of the variance, skewness and kurtosis of the statistical distribution, in terms of the *cumulants* at zero lags. We will use and refer to normalized quantities because they are shift and scale invariant.

COMPETITIVE LAYERS

The neurons in a competitive layer distribute themselves to recognize frequently presented input vectors. The competitive transfer function accepts a net input vector \mathbf{p} for a layer (each neuron competes to respond to \mathbf{p}) and returns outputs of 0 for all neurons except for the winner, which is associated with the most positive element of the net input. For zero bias, the neuron whose weight vector is closest to the input vector has the least negative net input and, therefore, wins the competition to output a 1.

The winning neuron will move closer to the input, after this has been presented. The weights of the winning neuron are adjusted with the *Kohonen* learning rule. If for example the i th-neuron wins, the elements of the i th-row of the input weight matrix (\mathbf{IW}) are adjusted as shown in Eq. (3):

$$\mathbf{IW}_i^{l+1}(q) = \mathbf{IW}_i^{l+1}(q-1) + \alpha [\mathbf{p}(q) - \mathbf{IW}_i^{l+1}(q-1)], \quad (3)$$

where \mathbf{p} is the input vector, q is the time instant, and α is the learning rate. The *Kohonen* rule allows the weights of a neuron to learn an input vector, so it is useful in recognition applications. The winning neuron is more likely to win the competition the next time a similar vector is presented. As more and more inputs are presented, each neuron in the layer closest to a group of input vectors soon adjusts its weight vector toward those inputs. Eventually, if there are enough neurons, every cluster of similar input vectors will have a neuron that outputs “1” when a vector in the cluster is presented.

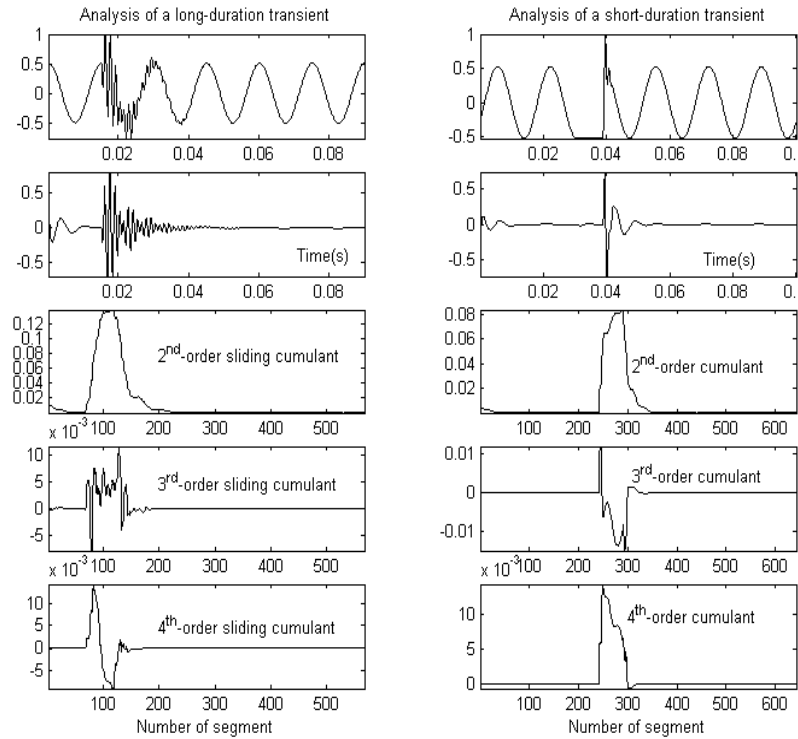

EXPERIMENTAL RESULTS

The aim is to differentiate between two classes of PQ *events*, named long-duration and short-duration. The experiment comprises two stages. The feature extraction stage is based on the computation of cumulants. Each vector's coordinate corresponds to the local maximum and minimum of the 4th-order central *cumulant*. Secondly, the classification stage is based on the application of the competitive layer to the feature vectors. We use a two-neuron competitive layer, which receives two-dimensional input feature vectors during the network training.

We analyze a number of 16 1000-point real-life registers during the feature extraction stage. Before the computation of the cumulants, two pre-processing actions have been performed over the sample signals. First, they have been normalized because they exhibit very different-in-magnitude voltage levels. Secondly, a high-pass digital filter (5th-order Butterworth model with a characteristic frequency of 150 Hz) eliminates the low frequency components which are not the targets of the experiment. This by the way increases the non-*Gaussian* characteristics of the signals, which in fact are reflected in the higher-order cumulants. Fig. 1 shows the comparison of the two types of *events*.

After pre-processing, a battery of sliding central cumulants (2nd, 3rd and 4th-order) is calculated. Each cumulant is computed over 50 points; this window's length (50 points) has been selected neither to be so long to cover the whole signal nor to be very short. The algorithm calculates the 3 central cumulants over 50 points, and then it jumps to the following starting

Figure 1. Analysis for two types of transients

point; as a consequence we have 98 percent overlapping sliding windows ($49/50=0.98$). Each computation over a window (called a segment) outputs 3 cumulants.

The signal processing analysis indicates that the 2nd-order cumulant sequence (the variance), clearly indicates the presence of an event. Both types of *transients* exhibit an increasing variance in the neighbourhood of the PQ event, that present the same shape, with only one maximum. The magnitude of this maximum is by the way the only available feature which can be used to distinguish different events from the second-order point of view.

Resulting from the classification stage, the bi-dimensional representation (2-dimensional feature vectors) suggests very intelligible 2-D graphs for 4th-order. 3rd-order diagrams don't show quite different clusters because maxima and minima are similar. It is possible to differentiate PQ *events* from the 3rd-order

perspective if we consider more features in the input vector (perhaps 3-D feature vectors), like the number of extremes (maxima and minima), and the order in which the maxima and the minima appear as time increases.

The sliding 4th-order cumulants exhibit clear differences, not only for the shape of the time-domain graphs, but also for the different location of minima, which suggest a clustering for the points in the 2-D feature space. Fig. 2 shows an example of 4th-order cumulant sequence comparison for the two types of *transients*. For each sample register (data record) the sliding 4th-order cumulants' sequence is calculated (as in Fig. 2). For each data record, the maximum and the minimum are detected and selected as a point in the feature space.

Fig. 3 presents the results of the training stage, using the *Kohonen* rule. The horizontal (vertical) axis cor-

Figure 2. Comparison of 4th-order cumulants' sequences for two types of transients

responds to the maxima (minima) values. Each cross in the diagram corresponds to an input vector and the circles indicate the final location of the weight vector (after learning) for the two neurons of the competitive layer. Before training, both weight vectors pointed to the asterisk, which is the initializing point (the midpoint of the input intervals).

The separation between classes (inter-class distance) is well defined. Both types of PQ events are clustered. The correct configuration of the clusters is corroborated during the simulation of the neural network, in which we have obtained an approximate classification accuracy of 97 percent. During the simulation, new signals (randomly selected from our data base) were processed using this methodology. The accuracy of the classification results increases with the number of data. To evaluate the confidence of the statistics a

significance test has been conducted. As a result, the number of measurements is significantly correct.

CONCLUSION

In this paper we have proposed an automatic method to detect and classify two PQ *transients*, named short and long-duration. The method comprises two stages. The first includes pre-processing (normalizing and filtering) and outputs the 2-D feature vectors, each of which coordinate corresponds to the maximum and minimum of the central cumulants. The second stage uses a neural network to classify the signals into two clusters. This stage is different-in-nature from the one used in (Gerek et. al., 2006) consisting of quadratic classifiers. The configuration of the clusters is assessed

Figure 3. Competitive layer training results over 20 epochs. Upper cluster: Short-duration PQ-events. Down cluster: Long-duration events.

during the simulation of the network, in which we have obtained acceptable classification accuracy.

ACKNOWLEDGMENT

We would like to acknowledge the Spanish Ministry of Education and Science for funding the projects DPI2003-00878 and PETRI-95-0824-OP, and to the Andalusian Government for funding the project PAI2005-TIC00155.

KEY TERMS

Artificial Neural Networks: A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Cluster: A set of incidences relative to the characteristics associated to some signals, which have been previously analyzed.

Cumulants: Statistics that characterize a probability distribution. A distribution with given cumulants can be approximated through the Edgeworth series.

Competitive Layer: The neurons in a competitive layer distribute themselves to recognize frequently presented input vectors.

HOS: Higher-Order Statistics; the set of statistics of order higher than 2. The advantage of using them is based on the advantage of noise rejection for symmetrically distributed processes.

Power Quality: Is the branch of research which aims to study the techniques for the assessment of the quality of electricity.

Transient: A signal which vanishes with the time and usually with short duration. They are very common in industry applications. *Transients* may occur either in repeatable fashion or as random impulses.

Neural Networks on Handwritten Signature Verification

J. Francisco Vargas

Miguel A. Ferrer

University of Las Palmas de Gran Canaria, Spain

INTRODUCTION

Biometric offers potential for automatic personal identification and verification, differently from other means for personal verification; biometric means are not based on the possession of anything (as cards) or the knowledge of some information (as passwords). There is considerable interest in biometric authentication based on automatic signature verification (ASV) systems because ASV has demonstrated to be superior to many other biometric authentication techniques e.g. finger prints or retinal patterns, which are reliable but much more intrusive and expensive. An ASV system is a system capable of efficiently addressing the task of make a decision whether a signature is genuine or forger. Numerous pattern recognition methods have been applied to signature verification. Among the methods that have been proposed for pattern recognition on ASV, two broad categories can be identified: memory-based and parameter-based methods as a neural network. The Major approaches to ASV systems are the template matching approach, spectrum approach, spectrum analysis approach, neural networks approach, cognitive approach and fractal approach.

The proposed article reviews ASV techniques corresponding with approaches that have so far been proposed in the literature. An attempt is made to describe important techniques especially those involving ANNs and assess their performance based on published literature. The paper also discusses possible future areas for research using ASV.

BACKGROUND

As any human production, handwriting is subject to many variations from very diverse origins: Historic, geographic, ethnic, social, psychological, etc (Bou-

letreau, 1998). ASV is a difficult problem because signature samples from the same person are similar but not identical. In addition, a person signature often changes radically during their lifetime (Hou, 2004). Although these factors can affect a given instance of a person writing, writing style develops as the writer learns to write, as do consistencies which are typically retained (Guo, 1997). One of the methods used by expert document examiners is to try to exploit these consistencies and identify ones which are both stable and difficult to imitate. In general, ASV systems can be categorized into two kinds: The On-line and Off-line systems. For On-line, the use of electronic devices to capture dynamics from signature permits to register more information about the signing process while improving the system performance, in the case of Off-line approaches for ASV, this dynamic information is lost and only a static image is available. This makes it quit difficult to define effective global or local features for the verification purpose.

Three different types of forgeries are usually take into account on ASV system: random forgeries, produced without knowing either the name of the signer nor the shape of his signature; simple forgeries, produced knowing the name of the signer but without having an example of his signature; and skilled forgeries, produced by people who, looking at an original instance of the signature, attempt to imitate it as closely as possible. The problem of signature verification become more difficult when passing from random to simple and skilled forgeries, the later being so difficult a task that even human beings make errors in several cases. It is pointing out that several systems proposed up to now, while performing reasonably well on a single category of forgeries, decrease in performance when working with all the categories simultaneously, and generally this decrement is bigger than one would expect.(Abuhaiba,2007; Ferrer,2005).

Numerous pattern recognition methods have been applied to signature verification (Plamondon, 1989). Among the methods that have been proposed for pattern recognition, two broad categories can be identified: memory-based techniques in which incoming patterns are matched to a (usually large) dictionary of templates, and parameter-based methods in which pre-processed patterns are sent to a trainable classifier such as a neural network (Lippmann, 1987). Memory-based recognition methods require a large memory space to store the templates, while a neural network is a parameter-based approach which just requires a small amount of memory space to store the linking weights among neurons. Mighell et al (Mighell, 1989) were apparently the first to work in applying NNs for off-line signature classification. Sabourin and Drouhard (Sabourin, 1992) presented a method based on directional probability density functions together with a BackPropagation neural networks (BPN) to detect random forgery. Qi and Hunt (Qi, 1996) used global and grid features with a simple Euclidean distance classifier. Sansone and Vento (Sansone, 2000) proposed a sequential three-stage multi-expert system, in which the first expert eliminates random and simple forgeries, the second isolates skilled forgeries, and the third gives the final decision by combining decisions of the previous stages together with reliability estimations. Baltzakis and Papamarkos (Baltzakis, 2001) developed a two-stage neural network, in which the first stage gets the decisions from neural networks and Euclidean distance classifiers supplied by the global, grid and texture features, and the second combines the four decisions using a radial-base function (RBF) neural network.

MAIN FOCUS OF THE CHAPTER

As mentioned above, the major approaches to signature verification systems are the template matching approach, spectrum approach, spectrum analysis approach, neural networks approach, cognitive approach and fractal approach. The rigid template matching, the simplest and earliest approach to pattern recognition, can detect random forgeries from genuine signatures successfully, but cannot detect skilled forgeries effectively. The statistical approach, including HHMs, Bayesian and so on, can detect random forgeries as well as skilled forgeries from genuine ones. Structural approach shows good performance when detecting

genuine signatures and forgeries. But this approach may yield a combinatorial explosion of possibilities to be investigated, demanding large training sets and very large computational efforts. The spectrum analysis approach can be applied to different languages, including English and Chinese. Moreover it can be applied to either on-line or off-line verification systems.

Neural networks approach offers several advantages such as, unified approaches for feature extraction and classification and flexible procedures for finding good, moderately nonlinear solutions. When it is used in either on-line or off-line signature verification, it also shows reasonable performance.

Neural Networks on ASV

Multi-layer perceptron (MLP) neural networks are among the most commonly used classifiers for pattern recognition problems. Despite their advantages, they suffer from some very serious limitations that make their use, for some problems, impossible. The first limitation is the size of the neural network. It is very difficult, for very large neural networks, to get trained. As the amount of the training data increases, this difficulty becomes a serious obstacle for the training process. The second difficulty is that the geometry, the size of the network, the training method used and the training parameters depend substantially on the amount of the training data. Also, in order to specify the structure and the size of the neural network, it is necessary to know a priori the number of the classes that the neural network will have to deal with. Unfortunately, when talking about a useful ASV, a priori knowledge about the number of signatures and the number of the signature owners is not available (Baltzakis, 2001).

For the BPN case, a learning law is used to modify weight values based on an output error signal propagated back through the network. From random initial values, the weights are changed according to this learning law that uses a learning rate and a smoothing rate which sometimes allows a faster convergence of the training phase. The training phase is critical, especially when the data to be classified are not clearly distinguishable and when there are not enough examples to conduct training. In this case, the training phase can be very long and it may even be impossible to obtain an acceptable performance. Usually a criterion for stopping the training phase is defined. After that, several rejection methods are evaluated to improve the decision taken by

this kind of classifier. Finally, the number of neurons in the hidden layer of the BPN is adjusted in order to increase the global performance of the first stage of the ASV (Drouhard, 1996).

An interesting aspect of BPN is that during learning process, the hidden layers build an internal representation of the inputs that is useful to produce the output (Looney, 1997). (Fleming, 1990) used a two-stage NN with the same number of neurones for input and output layers, and fewer units for the hidden layer. This forces the network to encode the inputs in a smaller dimensional space retaining most of the relevant information in an equivalent way as the Principal Component Analysis (PCA) method. This class of networks are known as compression networks. An important property of compression networks is that they can act as auto associative or content addressable memories (Kohonen, 1977; Valentin, 1994). This means that these networks are able to acceptably reconstruct a degraded pattern when noise is given as input or to complete an incomplete input pattern (O'Toole, 1993). The quality of the results will depend on the number of hidden units of the compression network.

On the other hand, Syntactic NNs can model stochastic and non-stochastic grammars. Learning is therefore a process of grammatical inference and recognition a process of parsing. Note that this has great generality; by varying the grammar we can encompass a wide range of pattern recognition models. The stochastic nets are properly probabilistic and are powerful discriminators; the non-stochastic are less powerful, but have straightforward silicon implementation with existing technology. Learning in syntactic nets may proceed supervised or unsupervised (Lucas, 1990).

Combined Classifiers Approaches

(Baltzakis, 2001) presents a different technique for off-line signature recognition and verification. The proposed confronts above mentioned BPN problems by reducing the training computation time (This is achieved because each neural network corresponds to only one signature owner) and the size of the neural networks used (The feature set is split to three different groups, i.e., global features, grid features and texture features.). For each one of these feature sets a special two stage Perceptron OCON (one-class-one-network) classification structure has been implemented. In the

first stage, the classifier combines the decision results of the neural networks and the Euclidean distance obtained using the three feature sets. The results of the first-stage classifier feed a second-stage radial base function (RBF) neural network structure, which makes the final decision.

To effectively verify skilled forgeries, a fuzzy neural network named *Pseudo Outer-Product based Fuzzy Neural Network* (POPFNN) is integrated into the signature verification system described in (Zhou, 1996). As a hybrid of fuzzy systems and neural networks, the POPFNN possesses many advantages such as high computational capability and learning ability when compared against other techniques used in signature verification systems. As hybrid intelligent systems, fuzzy NNs possess the advantages of both NNs and fuzzy rule-based systems and are particularly powerful in handling complex, non-linear and imprecise problems such as ASV. Besides, the membership functions and fuzzy rules identified in the POPFNN give more transparency to the decision making process. These advantages make the proposed fuzzy neural network driven signature verification system particularly powerful and robust even in dealing with skilled forgeries. In (Zhou, 1996), POPFNN operates in two fundamental modes, the learning mode and the classification mode. In the learning mode, a collection of training signature samples is used to train POPFNN. Feature vectors extracted from the training signature samples are utilized to initialize and adjust the parameters of POPFNN, including membership functions, fuzzy rules, and weights of the links. In the classification mode, POPFNN performs pure classification without self-modification. Feature vectors extracted from the unknown signatures are fed into POPFNN and the corresponding outputs are obtained at the output layer of POPFNN.

(Bromley, 1994) presents an algorithm based on a novel NN, called a "Siamese" neural network. This network has two input fields to compare two patterns and one output whose estate value corresponds to the similarity between the two patterns. During training the two sub-networks extract features from two signatures, while the joining neuron measures the distance between the two feature vectors. Training was carried out using a modified version of BP. All weights could be learnt, but the two sub-networks were constrained to have identical weights.

FUTURE TRENDS

Notwithstanding the enormous work carried out in the field of signature verification, several questions still remains unresolved. New solutions to these problems will determine the conditions under which the signature verification systems of the next future will be developed. The selection of the most suitable set of feature for a signer is one of the relevant open questions and the use of new approaches for classification still an open problem. Genetic algorithms (GA) have been recently used for this purpose (Xuhua, 1996). Another promising area of research concern multi-expert verification, which combine hard (Dimauro, 1997) and soft (Plamondon, 1992) decision, based on parallel (Qi, 1995), serial (Cardot, 1991) or hybrid strategies (Cordella, 2000).

In the framework of a handwritten text recognition application, (Heutte, 2004) have developed a multiple agent system able to manage interaction between different contextual levels of handwriting interpretation. The EMAC (Hernoux, 1999) environment has been specified from constraints imposed by their handwriting interpretation system. This work presents this platform as help to implement specific collaboration or cooperation schemes between agents which bring out new trends in the automatic reading of handwritten texts and could be implemented for automatic signature verification systems.

(Balkrishana, 2007) recently presented a Colour Code Algorithm which deals with the recognition of the signature, as human operator generally make the work of signature recognition. Hence the algorithm simulates human behavior, to achieve perfection and skill through AI. The logic that decides the extent of validity of the signature must implement Artificial Intelligence Pattern recognition is the science that concerns the description or classification of measurements, usually based on underlying model. In future the system can be configured using Neural Networks and Fuzzy Rule base, where online training of recognition is possible.

A list of companies involved in signature verification systems production is given in (Kalenova, 2004), along with a short description of the products available. Although signature verification is not one of the safest biometric solutions, the use of it in business practices is still justified. Primarily due to the fact that the signature

is a de facto mean of confirming the identity of the person, and therefore will provide a far less disruptive migration to an advanced technology than any other biometric can. Thus, signature verification has a very promising future.

CONCLUSION

Automatic signature verification is very attractive problem for researches. This article presents a review of approaches for Automatic Signature Verification using Neural Networks. The main aspects related to training process are discussed. Although some approaches have False Reject Rate and False Acceptance Rate ranging from 2% to 5%, systems developers cannot compare their results due to the lack of a widely accepted protocol for experimental tests, as well as the absence of large, public signature databases. A useful bibliography is also provided for interested readers.

KEY TERMS

Agent Based Mode: A specific individual based computational model for computer simulation extensively related to the theme in complex systems, Monte Carlo Method, multi agent systems, and evolutionary programming. The idea is to construct the computational devices (agents with some properties) and then, simulate them in parallel to model the real phenomena.

Automatic Signature Verification: A procedure that determine if a handwritten signature is genuine or a forgery, when a person claims for identity verification.

Backpropagation Algorithm: Learning algorithm of ANNs, based on minimising the error obtained from the comparison between the outputs that the network gives after the application of a set of network inputs and the outputs it should give (the desired outputs).

Feature Selection: The technique, commonly used in machine learning, of selecting a subset of relevant features for building robust learning models. Its objective is three-fold: improving the prediction performance of the predictors, providing faster and more cost-effective predictors, and providing a better understanding of the underlying process that generated the data.

Fuzzy Logic: Derived from fuzzy set theory dealing with reasoning that is approximate rather than precisely deduced from classical predicate logic. It can be thought of as the application side of fuzzy set theory dealing with well thought out real world expert values for a complex problem.

Genetic Algorithms: A genetic algorithm is technique used for searching or programming. It is used in computing to find true or approximate solutions to optimization and search problems of various types and used as a function in evolutionary computation. Genetic algorithms are based on biological events. They mimic biological evolution.

Principal Component Analysis: A technique used to reduce multidimensional data sets to lower dimensions for analysis. PCA involves the computation of the eigenvalue decomposition of a data set, usually after mean centering the data for each attribute.

Neural/Fuzzy Computing Based on Lattice Theory

Vassilis G. Kaburlasos

Technological Educational Institution of Kavala, Greece

INTRODUCTION

Computational Intelligence (CI) consists of an evolving collection of methodologies often inspired from nature (Bonissone, Chen, Goebel & Khedkar, 1999, Fogel, 1999, Pedrycz, 1998). Two popular methodologies of CI include neural networks and fuzzy systems.

Lately, a unification was proposed in CI, at a “data level”, based on lattice theory (Kaburlasos, 2006). More specifically, it was shown that several types of data including vectors of (fuzzy) numbers, (fuzzy) sets, 1D/2D (real) functions, graphs/trees, (strings of) symbols, etc. are partially (lattice)-ordered. In conclusion, a unified cross-fertilization was proposed for knowledge representation and modeling based on lattice theory with emphasis on clustering, classification, and regression applications (Kaburlasos, 2006).

Of particular interest in practice is the totally-ordered lattice (\mathbb{R}, \leq) of real numbers, which has emerged historically from the conventional measurement process of successive comparisons. It is known that (\mathbb{R}, \leq) gives rise to a hierarchy of lattices including the lattice (\mathbb{F}, \leq) of *fuzzy interval numbers*, or FINs for short (Papadakis & Kaburlasos, 2007).

This article shows extensions of two popular neural networks, i.e. *fuzzy-ARTMAP* (Carpenter, Grossberg, Markuzon, Reynolds & Rosen 1992) and *self-organizing map* (Kohonen, 1995), as well as an extension of conventional *fuzzy inference systems* (Mamdani & Assilian, 1975), based on FINs. Advantages of the aforementioned extensions include both a capacity to rigorously deal with nonnumeric input data and a capacity to introduce tunable nonlinearities. *Rule induction* is yet another advantage.

BACKGROUND

Lattice theory has been compiled by Birkhoff (Birkhoff, 1967). This section summarizes selected results regard-

ing a Cartesian product lattice $(L, \leq) = (L_1, \leq_1) \times \dots \times (L_N, \leq_N)$ of *constituent* lattices (L_i, \leq_i) , $i=1, \dots, N$.

Given an *isomorphic* function $\theta_i: (L_i, \leq_i) \rightarrow (L_i, \leq_i)^\partial$ in a constituent lattice (L_i, \leq_i) , $i=1, \dots, N$, where $(L_i, \leq_i)^\partial \equiv (L_i, \leq_i^\partial)$ denotes the *dual* (lattice) of lattice (L_i, \leq_i) , then an isomorphic function $\theta: (L, \leq) \rightarrow (L, \leq)^\partial$ is given by $\theta(x_1, \dots, x_N) = (\theta_1(x_1), \dots, \theta_N(x_N))$.

Given a *positive valuation* function $v_i: (L_i, \leq_i) \rightarrow \mathbb{R}$ in a constituent lattice (L_i, \leq_i) , $i=1, \dots, N$ then a positive valuation $v: (L, \leq) \rightarrow \mathbb{R}$ is given by $v(x_1, \dots, x_N) = v_1(x_1) + \dots + v_N(x_N)$.

It is well-known that a positive valuation $v_i: (L_i, \leq_i) \rightarrow \mathbb{R}$ in a lattice (L_i, \leq_i) implies a metric function $d_i: L_i \times L_i \rightarrow \mathbb{R}_0^+$ given by $d_i(a, b) = v_i(a \vee b) - v_i(a \wedge b)$.

Minkowski metrics $d_p: (L_1, \leq_1) \times \dots \times (L_N, \leq_N) = (L, \leq) \rightarrow \mathbb{R}$ are given by

$$d_p(x, y) = \left[d_1^p(x_1, y_1) + \dots + d_N^p(x_N, y_N) \right]^{1/p},$$

where

$$x = (x_1, \dots, x_N), y = (y_1, \dots, y_N), p \in \mathbb{R}.$$

An *interval* $[a, b]$ in a lattice (L, \leq) is defined as the set $[a, b] \doteq \{x \in L: a \leq x \leq b, a, b \in L\}$. Let $\tau(L)$ denote the set of intervals in a lattice (L, \leq) . It turns out that $(\tau(L), \leq)$ is a lattice, ordered by set inclusion.

Definition 1. The *size* $Z_p: \tau(L) \rightarrow \mathbb{R}_0^+$ of a lattice (L, \leq) interval $[a, b] \in \tau(L)$, with respect to a positive valuation $v: (L, \leq) \rightarrow \mathbb{R}$, is defined as $Z_p([a, b]) = d_p(a, b)$.

NEURAL/FUZZY COMPUTING BASED ON LATTICE THEORY

This section delineates modified extensions to a hierarchy of lattices stemming from the totally ordered lattice (\mathbb{R}, \leq) of real numbers. Then, it details the relevance of

novel mathematical tools. Next, based on the previous mathematical tools, this section presents extensions of ART/SOM/FIS. Finally, it discusses comparative advantages.

Modified Extensions in a Hierarchy of Lattices

Consider the product lattice $(\Delta, \leq) = (R \times R, \leq^\delta \times \leq) = (R \times R, \geq \times \leq)$ of *generalized intervals*. A *generalized interval* (element in Δ) will be denoted by $[a, b]$ and will be called *positive* (*negative*) for $a \leq b$ ($a > b$). The set of positive (negative) generalized intervals will be denoted by Δ_+ (Δ_-) – We remark that the set of *positive* generalized intervals is isomorphic to the set of *conventional intervals* in the set R of real numbers.

A *decreasing* function $\theta_R: R \rightarrow R$ is an isomorphic function $\theta_R: (R, \leq) \rightarrow (R, \leq)^\delta$; furthermore, a *strictly increasing* function $\nu_R: R \rightarrow R$ is a positive valuation $\nu_R: (R, \leq) \rightarrow R$. Hence, function $\nu_\Delta: (\Delta, \leq) \rightarrow R$ given by $\nu_\Delta([a, b]) = \nu_R(\theta_R(a)) + \nu_R(b)$ is a positive valuation in lattice (Δ, \leq) . There follows a metric function $d_\Delta: \Delta \times \Delta \rightarrow R_0^+$ given by $d_\Delta([a, b], [c, d]) = [\nu_R(\theta_R(a \wedge c)) - \nu_R(\theta_R(a \vee c))] + [\nu_R(b \vee d) - \nu_R(b \wedge d)]$; in particular, for $\theta_R(x) = -x$ and $\nu_R(x) = x$ it follows $\nu_\Delta([a, b]) = |a - c| + |b - d|$. Choosing *parametric* functions $\theta_R(\cdot)$ and $\nu_R(\cdot)$ there follow tunable nonlinearities in lattice (R, \leq) . Moreover, note that Δ is a *real linear space* with

- *addition* defined as $[a, b] + [c, d] = [a + c, b + d]$, and
- *multiplication* (by a real k) defined as $k[a, b] = [ka, kb]$.

It turns out that Δ_+ (as well as Δ_-) is *cone* in linear space Δ – Recall that a subset C of a linear space is called *cone* if for all $x \in C$ and $\lambda > 0$, we have $\lambda x \in C$.

Definition 2. A *generalized interval number* (GIN) is a function $f: (0, 1] \rightarrow \Delta$.

Let G denote the set of GINs. It follows that (G, \leq) is a lattice, in particular (G, \leq) is the Cartesian product of lattices (Δ, \leq) . Moreover, G is a *real linear space* with

- *addition* defined as $(G_1 + G_2)(h) = G_1(h) + G_2(h)$, $h \in (0, 1]$, and
- *multiplication* (by a real k) defined as $(kG)(h) = kG(h)$, $h \in (0, 1]$.

We remark that the cardinality of set G equals $\aleph_1^{\aleph_1} = (2^{\aleph_0})^{\aleph_1} = 2^{\aleph_0 \aleph_1} = 2^{\aleph_1} = \aleph_2 > \aleph_1$, where \aleph_1 is the cardinality of the set R of real numbers.

Proposition 3. Consider metric(s) $d_\Delta: \Delta \times \Delta \rightarrow R_0^+$ in lattice (Δ, \leq) . Let $G_1, G_2 \in (G, \leq)$. Assuming that the following integral exists, a metric function $d_G: G \times G \rightarrow R_0^+$ is given by

$$d_G(G_1, G_2) = \int_0^1 d_\Delta(G_1(h), G_2(h)) dh.$$

Our interest here focuses on the *sublattice* (F, \leq) of lattice (G, \leq) , namely sublattice of *fuzzy interval numbers* (FINs). A FIN is defined rigorously as follows.

Definition 4. A *fuzzy interval number* (FIN) F is a GIN such that either (1) both $F(h) \in \Delta_+$ and $h_1 \leq h_2 \Rightarrow F(h_1) \geq F(h_2)$, for all $h \in (0, 1]$ (*positive FIN*) or (2) there is a positive FIN P such that $F(h) = -P(h)$, for all $h \in (0, 1]$ (*negative FIN*).

Let F_+ (F_-) denote the set of positive (negative) FINs. Note that both $F_+ \cup F_- = F$ and $F_+ \cap F_- = \emptyset$ hold. Furthermore, F_+ (F_-) is a cone with cardinality \aleph_1 (Kaburlasos & Kehagias, 2006). The previous mathematical analysis may potentially produce useful techniques based on lattice vector theory (Vulikh, 1967). A *positive FIN* will simply be called “FIN”. A FIN may admit different interpretations including a (fuzzy) number, an interval, and a cumulative distribution function.

Relevance of Novel Mathematical Tools

A fundamental mathematical result in *fuzzy set theory* is the “resolution identity theorem”, which states that a fuzzy set can, equivalently, be represented either by its membership function or by its α -cuts (Zadeh, 1975). The aforementioned theorem has been given little attention in practice to date. However, some authors have capitalized on it by designing effective as well as efficient fuzzy inference systems (FIS) involving fuzzy numbers whose α -cuts are conventional closed intervals (Uehara & Fujise, 1993, Uehara & Hirota, 1998).

This work builds on the abovementioned mathematical result as follows. In the first place, we drop the possibilistic interpretation of a membership function. Then, we consider the corresponding “ α -cuts representation”.

Next, we consider the metric cone F_+^N of (positive) FINs. In conclusion, we propose extensions of established neural/fuzzy algorithms, including *ART* (adaptive resonance theory), *SOM* (self-organizing map), and *FIS* (fuzzy inference systems), in F_+^N (Kaburlasos, 2007). A novelty of this work is an improved mathematical notation, which emphasizes relevance with the aforementioned “resolution identity theorem”.

An Extension of Fuzzy-ARTMAP

A fuzzy-ARTMAP extension, namely *fuzzy lattice reasoning (FLR)*, is presented in this section based on a similarity measure (function) defined in the following.

Definition 5. A similarity measure in a set S is a function $\mu: S \times S \rightarrow (0, 1]$, which satisfies the following conditions.

- (S1) $\mu(a, b) = 1 \Leftrightarrow a = b$.
- (S2) $\mu(a, b) = \mu(b, a)$.
- (S3) $\frac{1}{\mu(a, b)} + \frac{1}{\mu(x, x)} \leq \frac{1}{\mu(a, x)} + \frac{1}{\mu(x, b)}$.

A similarity measure is defined based on a metric function next.

Proposition 6. If function $d: S \times S \rightarrow \mathbb{R}_0^+$ is a metric then function $\mu: S \times S \rightarrow (0, 1]$ given by $\mu(a, b) = 1/[1 + d(a, b)]$ is a similarity measure.

FLR for Training

FLR-0: A set $RB = \{(u_1, C_1), \dots, (u_L, C_L)\}$ is given, where $u_l \in F_+^N$ and $C_l \in \mathbf{C}$, $l=1, \dots, L$ is a class label in the finite set \mathbf{C} .

FLR-1: Present the next input pair $(x_i, K_i) \in F_+^N \times \mathbf{C}$, $i=1, \dots, n$ to the initially “set” RB .

FLR-2: If no more pairs are “set” in RB then store input pair (x_i, K_i) in the RB ; $L \leftarrow L+1$; goto step FLR-1.

Else, compute the similarity $\mu(x_i, u_l)$ of input $x_i \in F_+^N$ with a “set” element $u_l \in F_+^N$, $l=1, \dots, L$ in RB .

FLR-3: Competition among the “set” pairs in the RB : Winner is pair (u_j, C_j) such that $J \doteq \arg \max_{l \in \{1, \dots, L\}} \mu(x_i, u_l)$. In case of multiple winners, choose the one with the smallest size $Z_1(\cdot)$.

FLR-4: *Assimilation Condition*: Both (1) size $Z_1(x_i \vee u_j)$ is less than a user-defined threshold size Z_{crit} , and (2) $K_i = C_j$.

FLR-5: If the *Assimilation Condition* is not satisfied then “reset” the winner pair (u_j, C_j) ; goto step FLR-2.

Else, replace the winner u_j by the join-interval $x_i \vee u_j$; goto step FLR-1.

The corresponding testing phase is carried out by winner-take-all competition based on the similarity measure function $\mu(\cdot, \cdot)$.

An Extension of SOM

A straightforward SOM extension, namely *granular SOM (grSOM)*, is presented in this section in cone F_+^N .

grSOM for Training

GR-0: The user defines the size L of a $L \times L$ grid of neurons. Each neuron can store both a N -dimensional FIN $W_{ij} \in F_+^N$, $i, j \in \{1, \dots, L\}$ and a class label $C_{ij} \in \mathbf{C}$, where \mathbf{C} is a finite set. Initially all neurons are *uncommitted*.

GR-1: Memorize the first training data pair $(x_1, K_1) \in F_+^N \times \mathbf{C}$ by committing, randomly, a neuron in the $L \times L$ grid.

Repeat the following steps a user-defined number N_{epochs} of epochs.

GR-2: For each training datum $(x_k, K_k) \in F_+^N \times \mathbf{C}$, $k=1, \dots, n$ “reset” all $L \times L$ grid neurons. Then carry out the following computations.

GR-3: Calculate the Minkowski metric distance $d_1(x_k, W_{ij})$ between x_k and *committed* neurons W_{ij} , $i, j \in \{1, \dots, L\}$.

GR-4: Competition among the “set” (and, *committed*) neurons in the $L \times L$ grid: Winner is neuron (I, J) whose weight W_{IJ} is the nearest to x_k , that is $(I, J) \doteq \arg \min_{i, j \in \{1, \dots, L\}} d_1(x_k, W_{i, j})$.

GR-5: *Assimilation Condition*: Both (1) Vector W_{ij} is in the neighborhood of vector W_{IJ} on the $L \times L$ grid, and (2) $C_{IJ} = K_k$.

GR-6: If the *Assimilation Condition* is satisfied then compute a new value W'_{ij} as

$$W'_{ij} \doteq \left[1 - \frac{h(k)}{1 + d_1(W_{i,j}, W_{i,j})} \right] W_{i,j} + \frac{h(k)}{1 + d_1(W_{i,j}, W_{i,j})} x_k$$

Else, “reset” the winner (I,J); goto GR-4.

GR-7: If all the $L \times L$ neurons are “reset” then commit an *uncommitted* neuron from the grid, and memorize the current training datum (x_k, K_k) .

If there are no more *uncommitted* neurons then increase L by one.

The corresponding testing phase is carried out by winner-take-all competition based on the Minkowski metric $d_1(.,.)$.

An Extension of FIS

The basic idea towards novel FIS analysis and design is to employ a similarity measure function $\mu(X, A_i) = 1/[1 + d(X, A_i)]$, where $X, A_i \in F_+^N$, as a fuzzy membership function regarding a rule $R_i: A_i \rightarrow C_i$, where $A_i \in F_+^N$, $C_i \in F_+^M$, $i=1, \dots, L$ (Kaburlasos & Kehagias, 2007). Advantages are presented in the following.

Comparative Advantages

First, an important advantage of the mathematical tools above is that the proposed ART/SOM/FIS extensions can handle, in any combination, numeric and/or non-numeric data, the latter include fuzzy numbers, intervals, and cumulative distribution functions.

Second, we can employ parametric decreasing (increasing) functions $\theta_R: R \rightarrow R$ ($v_R: R \rightarrow R$) in a data dimension, where the function parameters can be estimated/tuned optimally towards improving performance.

Third, the proposed ART/SOM/FIS extensions can induce descriptive decision-making knowledge (i.e. rules) from the training data.

Fourth, regarding the FLR, note that a *similarity measure* function $\mu(.,.)$ can effectively replace an *inclusion measure* function $\sigma(.,.)$ —Recall that the latter (function) had replaced both of fuzzy-ARTMAP’s *Choice* (Weber) function and *Match* function (Kaburlasos & Petridis, 2000, Kaburlasos, Athanasiadis & Mitkas, 2007). The reason behind the aforementioned “effective” replacement is that an *inclusion measure* $\sigma(A, B)$, or $\sigma(B, A)$, considers mainly one of $A, B \in F_+^N$; whereas,

a *similarity measure* $\mu(A, B)$ considers both $A, B \in F_+^N$ based on their corresponding metric distance.

Fifth, regarding the proposed SOM extension, note that this work carries out computations in the cone F_+ of FINs for faster data processing compared to a previous version of grSOM (Kaburlasos & Papadakis, 2006).

Sixth, regarding the proposed FIS, novel advantages include a capacity to generalize beyond a fuzzy rule’s support. The latter implies, potentially, an alleviation of the “curse of dimensionality” problem regarding the number of rules.

FUTURE TRENDS

Data-processing of FINs by multiplayer perceptrons is straightforward, as described in (Kaburlasos & Christoforidis, 2006), and it will be pursued in future work.

CONCLUSION

This article has presented novel mathematical tools for unified analysis and design of neural/fuzzy systems. We built on fuzzy set theory’s “resolution identity theorem”. Nevertheless, in the first place, we dropped the possibilistic interpretation of a membership function. Then, we considered the corresponding “ α -cuts representation”. Our interest focused on fuzzy interval numbers, or FINs for short, which can represent (fuzzy) numbers, intervals, and cumulative distribution functions. Based on lattice theory, we showed that the space of FINs is a metric cone. In conclusion, this works opens up the possibility to design FIN-to-FIN maps implementable on neural/fuzzy architectures including also tunable nonlinearities.

KEY TERMS

ART: ART stands for Adaptive Resonance Theory. That is a biologically inspired neural paradigm for, originally, clustering binary patterns. An analog pattern version of ART, namely *fuzzy-ART*, is applicable in the unit hypercube. The corresponding neural network for classification is called *fuzzy-ARTMAP*.

Dual (Lattice): Given a lattice (L, \leq) , its *dual* lattice, symbolically $(L, \leq)^\circ$ or $(L, \leq^\circ) \equiv (L, \geq)$, is a lattice with the inverse order relation (\geq) .

FIS: FIS stands for Fuzzy Inference System. That is an architecture for reasoning involving fuzzy sets (typically fuzzy numbers) based of fuzzy logic.

Isomorphic (Function): Given two lattices (L_1, \leq_1) and (L_2, \leq_2) , an *isomorphic* function is a bijective (one-to-one) function $\varphi: (L_1, \leq_1) \rightarrow (L_2, \leq_2)$ such that $x \leq_1 y \Leftrightarrow \varphi(x) \leq_2 \varphi(y)$.

Lattice: A *lattice* is a poset (L, \leq) any two of whose elements have both a greatest lower bound (g.l.b.), denoted by $x \wedge y$, and a least upper bound (l.u.b.), denoted by $x \vee y$.

Poset: A *partially ordered set* (or, *poset*, for short) is a pair (P, \leq) , where P is a set and \leq is an order relation on P . The latter (relation) by definition satisfies (1) $x \leq x$, (2) $x \leq y$ and $y \leq x \Rightarrow x = y$, and (3) $x \leq y$ and $y \leq z \Rightarrow x \leq z$.

Positive Valuation (Function): Given a lattice (L, \leq) , a *positive valuation* is a function $v: (L, \leq) \rightarrow$

R , which satisfies both $v(x) + v(y) = v(x \wedge y) + v(x \vee y)$ and $x < y \Rightarrow v(x) < v(y)$.

Rule Induction: Process of learning, from cases or instances, if-then rule relationships that consist of an antecedent (if-part, defining the preconditions or coverage of the rule) and a consequent (then-part, stating a classification, prediction, or other expression of a property that holds for cases defined in the antecedent).

SOM: SOM stands for Self-Organizing Map. That is a biologically inspired neural paradigm for clustering analog patterns. SOM is often used for visualization of nonlinear relations of multi-dimensional data.

Sublattice: A *sublattice* (S, \leq) of a lattice (L, \leq) is another lattice such that both $S \subseteq L$ and $x, y \in S \Rightarrow x \wedge y, x \vee y \in S$.

A New Self-Organizing Map for Dissimilarity Data

Tien Ho-Phuoc

GIPSA-lab, France

Anne Guerin-Dugue

GIPSA-lab, France

INTRODUCTION

The **Self-Organizing Map** (Kohonen, 1997) is an effective and a very popular tool for data clustering and visualization. With this method, the input samples are projected into a low dimension space while preserving their topology. The samples are described by a set of features. The input space is generally a high dimensional space R^d . 2D or 3D maps are very often used for visualization in a low dimension space (2 or 3).

For many applications, usually in psychology, biology, genetic, image and signal processing, such vector description is not available; only pair-wise **dissimilarity** data is provided. For instance, applications in Text Mining or ADN exploration are very important in this field and the observations are usually described through their proximities expressed by the “Levenshtein”, or “String Edit” distances (Levenshtein, 1966). The first approach consists of the transformation of a dissimilarity matrix into a true **Euclidean distance** matrix. A straightforward strategy is to use “Multidimensional Scaling” techniques (Borg & Groenen, 1997) to provide a feature space. So, the initial vector SOM algorithm can be naturally used. If this transformation involves great distortions, the initial vector model for SOM is no longer valid, and the analysis of dissimilarity data requires specific techniques (Jain & Dubes, 1988; Van Cutsem, 1994) and Dissimilarity Self Organizing Map (DSOM) is a new one.

Consequently, adaptation of the **Self-Organizing Map** (SOM) to dissimilarity data is of a growing interest. During this last decade, different propositions emerged to extend the vector SOM model to pair-wise dissimilarity data. The main motivation is to cope with large proximity databases for data mining. In this article, we present a new adaptation of the SOM algorithm which is compared with two existing ones.

BACKGROUND

Basically, there are two main approaches to the SOM extension dealing with **dissimilarity** data. The first one uses a probabilistic framework, as for example in Graepel & Obermayer (1999) where a topographic mapping of proximity is derived by simulated annealing. The second approach uses directly the initial SOM framework to adapt the two usual steps (affectation, representation) to dissimilarity data, as for example in Kohonen & Somervuo (1998, 2002), in El Golli, Conan-Guez & Rossi (2004), and in Ambroise & Govaert, (1996).

Our work is inspired by this last approach and we have compared our proposal to the algorithms proposed by Kohonen (Kohonen & Somervuo, 1998) (Kohonen & Somervuo, 2002) and by El Golli et al. (El Golli, Conan-Guez & Rossi, 2004). Three metrics for quality estimate (quantization and neighborhood) are used for comparison. Numerical experiments on artificial and real data show the quality of the algorithm. The strong point of the proposed algorithm comes from a more accurate prototype estimate which is one of the most difficult parts of Dissimilarity SOM algorithms.

The major difficulty of the DSOM is the constraint on the output data representation. For (vector) SOM algorithm, there is a latent data model for each output **prototype** (a spherical distribution whose the prototype is the barycentre). For DSOM, there is no data model for each output prototype. One referent observation is explicitly associated to each output prototype instead of its tuning by the barycentre processing. This referent is usually chosen among the input observations at the end of an optimization process. Consequently, several prototypes can unfortunately share the same referent and these collisions provide great distortions in the output map. To avoid this difficulty, we propose here

an implicit referent for each prototype which is adapted during training iterations. So there is no collision during learning phase and consequently, the projection quality is greatly enhanced.

ADAPTATION OF SOM FOR DISSIMILARITY DATA

This article presents a new DSOM algorithm for dissimilarity data. We will first present DSOM algorithms which have been directly derived from the initial SOM framework. In the next parts, we will present in detail our proposed algorithm and some experiments to show its effectiveness in comparison with the other DSOM algorithms.

Description of DSOM Algorithms

Basically the starting point of the DSOM algorithm is the “batch” algorithm of the initial vector SOM. Let us recall this “batch” algorithm. At each iteration, the entire dataset is presented. We consider a dataset X of N observations, $X = \{o_i, i = 1..N\}$. The SOM is configured with C nodes (neurons) a priori interconnected on the output map where $\delta(c, l)$ is the distance between the nodes c and l . At iteration t , each node is represented by a prototype ω_c^t in the input space. After an initialization step, an affectation step and a representation step are sequentially processed at each iteration. The role of the former is to assign to each observation o_i , the best matching unit $\omega_{c^*}^t$, according to the **Euclidean distance**. The affectation function is:

$$c^* = \text{Arg} \left[\text{Min} \left(d^2(o_i, \omega_c) \right) \right] \quad (1)$$

Thus, a partition of the whole dataset is realized. In the latter, the prototype ω_c is adjusted to represent each **partition** X_c as well as possible. This prototype is computed as the weighted average of the input samples. The weights are evaluated through the **neighborhood function** $h^T(.)$ which is a non-increasing function of the distance on the map and controlled by a radius parameter $T(t)$ decreasing with time. At the end, the prototype ω_c is the gravity centre of the partition X_c .

This representation step cannot be directly transposed to dissimilarity data. An alternative implementation is to approximate these C prototypes by referent

observations belonging to the initial dataset X . Then, this step becomes very time-consuming: all the input observations are candidate and must be evaluated. Some strategies to reduce the computation time have been proposed (Conan-Guez, Rossi & El Golli, 2006).

Let us notice $D = [d_{ij}]$ $i, j = 1..N$, the dissimilarity data. These dissimilarities describe a non metric space. However, for all the DSOM algorithms, we consider symmetric dissimilarities.

For the DSOM proposed by Kohonen, each **prototype** will be represented by one referent observation, $\omega_c = o_{r(c)}$. During the initialisation step, C observations in the input dataset are randomly assigned to the prototypes. For the affectation step, the affectation function simply uses the input dissimilarity data. Each observation is assigned to the nearest prototype:

$$f(i) = \text{Arg} \left[\text{Min}_c \left(d_{ir(c)} \right) \right] = \text{Arg} \left[\text{Min}_c \left(d(o_i, o_{r(c)}) \right) \right] \quad (2)$$

For the representation step, a new observation $o_{r(c)}$ is assigned to the prototype ω_c minimizing the following cost function:

$$r(c) = \text{Arg} \left[\text{Min}_j \left(E(c, j) \right) \right] \quad (3)$$

where $E(c, j)$ is the weighted local distortion if o_j is the referent of the prototype ω_c :

$$E(c, j) = \sum_{o_i \in X} h^T(\delta(c, f(i))) d^2(o_j, o_i) \quad (4)$$

The global cost function which is then minimized is the global distortion over all the prototypes:

$$E_g = \sum_{c=1}^C E(c, r(c)) \quad (5)$$

For the representation step, different variants are possible. The neighborhood function in Eq. (4) can be simply integrated on the neighborhood of the prototype (the search is realized over the union of the partitions inside an output neighborhood) and not on the weighted dissimilarities. It is the “set Mean search”. Also, the exponent ‘2’ in Eq. (4) can be omitted: it is the “set **Median** search”.

Different prototypes can share the same referent (collision) when the search of the referent observa-

tions is limited to the input observations. So there is ambiguity for the affection step in the next iteration. This is the major difficulty of this approach. In some applications, for instance for symbol string organization, it is possible to search the “Median” or “Mean” outside the initial set: the referents in DSOM are not necessarily represented by elements belonging to the input space. But this optimization is an NP-hard problem. See Martínez, Juan & Casacuberta (2001) for a comparison of different strategies.

In El Golli, Conan-Guez & Rossi (2004), El Golli et al. propose a slightly different approach. The theoretical interest of this approach is the possibility to represent a prototype by more than one referent observation ($q \geq 1$). This allows to take into account a more complex latent data structure (multimodal distribution for instance) for each partition. Unfortunately in practice, it is difficult to choose the number (q) of referents by prototype and the optimization step becomes even more time-consuming. Let us describe here the algorithm for $q = 1$.

For the affectionation step, a distance between an observation and a prototype is defined in Eq. (6). When the **neighborhood** is decreasing, this distance converges towards the initial dissimilarity. The representation step is the same as previously. With convergence, these two algorithms are similar.

$$D^T(o_i, \omega_c) = \sum_{l=1}^C h^T(\delta(c, l)) \cdot d^2(o_i, o_{r(l)}) \quad (6)$$

Ambroise & Govaert (1996) proposes a different approach inspired from SEM (Stochastic Expectation Maximization) algorithm. The representation step is a “set Median search”. The assignation step uses a stochastic process to affect each observation to the prototypes by a multinomial distribution (the proportions depend on the neighbourhood function and the affectionation to the prototypes).

Description of the Proposed DSOM Algorithm

As explained previously, the difficulty is the representation step due to the lack of data model. The set of referent candidates is finite and distortions occur if several prototypes share the same referent. To overcome this

situation, we propose an implicit representation step. Let us remark, during training and until convergence, a referent observation is only used to define the distance between a prototype and an input observation. So, we will define a proximity measure $D^T(o_i, \omega_c)$ without explicit referent to the prototype ω_c . The representation phase will simply adapt this proximity considering the new partition of the observations and the update of the neighborhood function. This simple implementation has a counterpart: it is necessary to define a data model based on latent Euclidean assumptions.

Let us consider a set X of vector samples, $X = \{x_i, i = 1..N, x_i \in \mathbb{R}^d\}$. Let g be the gravity centre of X and $I(X)$, its **inertia**:

$$I(X) = \frac{1}{N} \sum_{x_i \in X} d^2(g, x_i)$$

All the samples have the same uniform weight ($\frac{1}{N}$). The inertia with respect to any observation e is then defined and decomposed thanks to the Huygens theorem:

$$I(X, e) = \frac{1}{N} \sum_{x_i \in X} d^2(e, x_i) = d^2(g, e) + I(X) \quad (7)$$

Moreover, $I(X)$ can be computed by considering all the distances $d(x_i, x_j)$:

$$I(X) = \frac{1}{N^2} \sum_{x_i \in X} \sum_{x_j \in X, j > i} d^2(x_i, x_j) \quad (8)$$

Thus, with Euclidean hypothesis, there is no need to know the gravity centre g , for computing the distance of any observation e to this gravity centre: $d^2(g, e) = I(X, e) - I(X)$.

We apply this principle to dissimilarity data. The input data is noticed o_i instead of x_i for vector data. The same formula is generalized to non uniform weighted observations. Let us consider one partition X_c associated to the **prototype** ω_c after the affectionation step. The proximity between an observation o_i and the prototype ω_c is then defined by using the weights $m_{j/c}$ for each observation o_j given the prototype ω_c . The **inertia** $I(X_c)$ is evaluated over all the weighted dissimilarities:

$$D^T(o_i, \omega_c) = I(X_c, o_i) - I(X_c) = \sum_{o_j \in X} m_{j/c} d^2(o_i, o_j) - I(X_c)$$

$$m_{j/c} = \frac{h^T(\delta(c, f(j)))}{\sum_{l=1}^N h^T(\delta(c, f(l)))}, \sum_{j=1}^N m_{j/c} = 1 \quad (9)$$

$$I(X_c) = \sum_{o_i \in X} \sum_{o_j \in X, j > i} m_{i/c} m_{j/c} d^2(o_i, o_j) \quad (10)$$

Therefore, the algorithm is the following:

- Initialization step: Having an initial **partition**, X_c , $c = 1..C$, with for instance, an affectation from an initial random referent observation set.
- Representation step: For all prototypes ω_c and observations o_i , compute the weights $m_{i/c}$ in Eq. (9) and the inertia $I(X_c)$ in Eq. (10), update the neighborhood function for the next iteration.
- Affectation step: Affect each observation to a prototype $\omega_{f(i)}$ according to the minimum distance in Eq. (9):

$$f(i) = \text{Arg} \left[\text{Min}_c \left(D^T(o_i, \omega_c) \right) \right]$$

The representation step and affectation step are sequentially computed up to convergence. The training parameters for the decreasing neighborhood function follow the usual recommendations for SOM algorithms: fast, then slow decrease (<http://www.cis.hut.fi/projects/somtoolbox/documentation/>).

With convergence, if necessary for visualization of the final map, a referent observation can be associated to each prototype according to a “set Mean search” (or set Median) or a “Mean search” (or Median), for instance.

In the following, we will compare three DSOM respectively called DSOM(K), DSOM(EG) and DSOM for our proposal. To compare the “set Mean” and “set Median” approaches for the three algorithms, $d^2(o_i, o_j)$ will be substituted by $d^{\gamma}(o_i, o_j)$: “set Median” corresponds to $\gamma = 1$ and “set Mean” to $\gamma = 2$. Different power values γ will be also tested. Other transformations may be applied to a dissimilarity matrix to transform it into a distance matrix, such as adding a constant, or combining the both (Joly & le Calvé, 1994). The “adding constant” method provides great distortions in the

initial dissimilarity data. Our experiments confirm it. The “power” method gives better results.

Concerning the computation time, these DSOM algorithms are equivalent, but the reasons differ. For DSOM(K) and DSOM(EG), the representation step is the most time-consuming one due to optimization for each referent. With our proposal, this optimization is implicit, but this step remains time-consuming because of the computation of the weights $m_{i/c}$ and inertia $I(X_c)$.

Methodology Description of the Experiment

To evaluate the 3 DSOM algorithms, two metrics will be used. The first one is the classical quantization error (E_g). The second one concerns topology preservation. Among existing criteria, we have chosen two measures in Eq. (11) which are compatible with **dissimilarity** data: the “trustworthiness” (M_1) and the “continuity” (M_2) (Venna & Kaski, 2001). The **trustworthiness** relates to the error provided by new observations in an output neighborhood while they are not in the input neighborhood; conversely for the **continuity**. M_1 and M_2 are evaluated in function of the number (k) of the nearest neighbors and normalized between 0 and 1. For visualization according to Venna & Kaski, the trustworthiness is more important than the continuity. The more $M_1(k)$ and $M_2(k)$ are large, the better the projection quality is. We compute also the integrated $M_i(k)$ until a neighborhood with 10% of the whole samples: these values (\bar{M}_i) measure the quality of the local topology preservation.

$$M_1(k) = 1 - \frac{2}{Nk(2N-3k-1)} \sum_{i=1}^N \sum_{o_j \in U_k(o_i)} (r(o_i, o_j) - k)$$

$$M_2(k) = 1 - \frac{2}{Nk(2N-3k-1)} \sum_{i=1}^N \sum_{o_j \in V_k(o_i)} (\hat{r}(o_i, o_j) - k) \quad (11)$$

With $C_k(o_i)$, $\hat{C}_k(o_i)$ sets of k first neighbors of o_i in the input space, output space;

$$U_k(o_i) = \{o_j \mid o_j \in \hat{C}_k(o_i) \wedge o_j \notin C_k(o_i)\},$$

$$V_k(o_i) = \{o_j \mid o_j \notin \hat{C}_k(o_i) \wedge o_j \in C_k(o_i)\},$$

$r(o_i, o_j)$, $\hat{r}(o_i, o_j)$ ranks of o_j in the neighbourhood of o_i in the input space, output space.

Three databases are used. The first one is an artificial dataset: 100 uniform samples in R^2 , dissimilarity data is the exact Euclidean distance, the configuration parameter γ is set to 2. The second one is the “Chicken Silhouette” (<http://algoval.essex.ac.uk:8080/data/sequence/chicken/chicken.tgz>). This data consists of 446 samples (binary images of chicken parts) categorized in 5 classes. The distance matrix is calculated according to “AngleCostFunction” (Barbara Spillmann, 2004) based on the local orientation of the sample contours. The third dataset is larger. It is extracted from the SCOWL word lists (<http://wordlist.sourceforge.net/>). After some reduction of plural and possessive forms from a small English dictionary, the dataset consists of 2000 words. The Levenshtein distance (Levenshtein, 1966) is then used to calculate the pair-wise dissimilarities.

Results

On the artificial dataset, the performances of the three algorithms are very similar (Table 1). With a vector SOM, the results are identical. The map is a hexagonal one with a grid of 5x5 neurons.

As expected, the behaviour of the three algorithms differs with the real datasets. With the “Chicken” databases, the map is a hexagonal one with a grid of 7x7 neurons. DSOM presents the best topology preservation according to $M_1(k)$ and $M_2(k)$ (Fig. 1.a), and the best compromise between quantization and topology preservation (Table 2). While varying γ , we observe an evolution of these criteria. We notice that each algorithm exhibits a different value for the optimal power γ : $\gamma = 1$ for DSOM(K), $\gamma = 1.5$ for DSOM(EG), $\gamma = 3$ for DSOM. However, $\gamma = 1$ can be considered as the best compromise for the three algorithms and will be used

Table 1. Comparison of the quantization quality (E_g) and topology preservation ($\overline{M_1}, \overline{M_2}$)

| Artificial, $\gamma = 2$ | DSOM(K) | DSOM(EG) | DSOM |
|--------------------------|---------|----------|--------|
| E_g | 0.0063 | 0.0067 | 0.0063 |
| $\overline{M_1}$ | 0.9892 | 0.9848 | 0.9855 |
| $\overline{M_2}$ | 0.9791 | 0.9777 | 0.9804 |

Table 2. Comparison of the quantization quality (E_g) and topology preservation ($\overline{M_1}, \overline{M_2}$)

| Chicken, $\gamma = 1$ | DSOM(K) | DSOM(EG) | DSOM |
|-----------------------|---------|----------|---------|
| E_g | 11.7183 | 12.0817 | 11.7966 |
| $\overline{M_1}$ | 0.8923 | 0.9040 | 0.9360 |
| $\overline{M_2}$ | 0.8320 | 0.8083 | 0.8880 |

Figure 1. (a) Chicken database: Evolution of $M_1(k)$ and $M_2(k)$ with $\gamma = 1$, (b) SCOWL database: Evolution of \overline{M}_1 and \overline{M}_2 for different values of the power γ

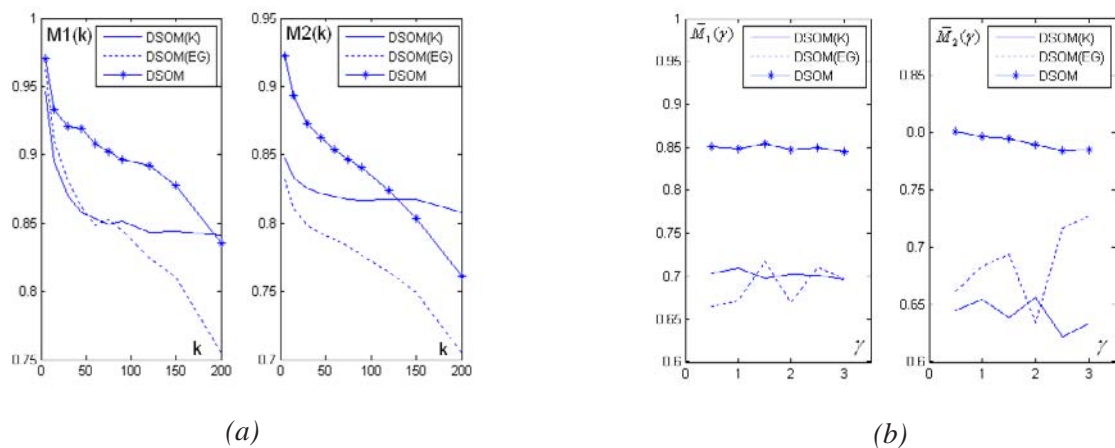

Figure 2. Chicken database: prototypes of the neurons for DSOM. Each color corresponds to one of five classes of chicken parts: wing, back, drumstick, thigh and back, and breast.

Figure 3. SCOWL database: Part of the final map. At the end, the referents are assigned with a “set Median search”. For the particularity of referent 117, see the text.

to present the results. Figure 2 show the prototypes of all the nodes for DSOM. The neighbor nodes have the similar prototypes. The map is organized to respect the data clustered into the 5 classes as well as possible.

For the third dataset, the hexagonal map is used with the grid of 12x12 neurons. The conclusions are the same. We present in Fig. 1.b, the evolution of the integrated $M_i(k)(\overline{M}_1)$. The values are higher for DSOM and also less sensible to different values of γ . Figure 3 illustrates the central part of the map for $\gamma = 1$, where the organization of the referents with length of the words is evident. On this figure, only referent 117 (“present”) does not belong to its partition. On the whole map, it is the case for 5 over 144 referents (3.5%). For DSOM(K) and DSOM(EG), the results are 23.4% and 99.7% respectively. From these characteristics, we also observe a higher effectiveness of the proposed algorithm which is mainly due to the implicit reference.

FUTURE TRENDS

The proposed algorithm is based on the computation of a “pseudo” gravity centre for each prototype. This computing is justified by assumption of existence of a latent Euclidean space. That means the dissimilarity data must be isometric to a L2 norm. In practice, this requirement is very seldom strictly checked and an approximation is often sufficient. Therefore, to completely validate this new DSOM, it is necessary to test it with more other data types and larger databases having a “ground truth”. The data organization is interpreted after projection into the final map, and the neighbourhood in the output map must reveal the main latent properties of the observations which must be in agreement with the “ground truth”.

CONCLUSION

This article presents a new affective algorithm for DSOM. Through the criteria of **trustworthiness** and **continuity**, this DSOM presents good topology preservation. The main reason of this improvement comes from the representation step where it is possible to continuously adapt the referent of each prototype like with the vector model. To achieve it, we use an implicit reference during the representation step thanks to the Huygens theorem. Even if the Euclidean assumptions are not exactly verified in practice, the distortions due to this mismatching are in fact less important than the ones occurred with the collision effect which is a difficult problem for the classical DSOM algorithms. This effectiveness is represented in this article by the better performance of the proposed algorithm compared to the other ones.

KEY TERMS

Affectation Step: A part of the learning iteration where an observation is affected to the nearest prototype according to a predefined distance.

Dissimilarity Data: Data in which all we know about the observations are pair-wise dissimilarities.

Dissimilarity SOM: A SOM where all observations are described by a dissimilarity matrix.

Prototype: Referent of a node (neuron) on the map.

Quantization Error: Error which appears when an observation is represented by a prototype.

Representation Step: A part of the learning iteration where the prototype is adapted to well represent its affected observations.

Self-Organizing Map (SOM): A subtype of artificial neural networks. It is trained using unsupervised learning to produce low dimensional representation of

the training samples while preserving the topological properties of the input space.

SOM Batch Algorithm: A version of SOM in which at an iteration all observations are available and used for computation.

Topology Preservation: Preservation of the neighbourhood relation of the observations in the output space. It means that the observations which are neighbours in the input space should be projected in neighbour nodes.

NLP Techniques in Intelligent Tutoring Systems

INTRODUCTION

Many Intelligent Tutoring Systems (ITSs) aim to help students become better readers. The computational challenges involved are (1) to assess the students' natural language inputs and (2) to provide appropriate feedback and guide students through the ITS curriculum. To overcome both challenges, the following non-structural Natural Language Processing (NLP) techniques have been explored and the first two are already in use: word-matching (WM), latent semantic analysis (LSA, Landauer, Foltz, & Laham, 1998), and topic models (TM, Steyvers & Griffiths, 2007).

This article describes these NLP techniques, the iSTART (Strategy Trainer for Active Reading and Thinking, McNamara, Levinstein, & Boonthum, 2004) intelligent tutor and the related Reading Strategies Assessment Tool (R-SAT, Magliano *et al.*, 2006), and how these NLP techniques can be used in assessing students' input in iSTART and R-SAT. This article also discusses other related NLP techniques which are used in other applications and may be of use in the assessment tools or intelligent tutoring systems.

BACKGROUND

Interpreting text is critical for intelligent tutoring systems (ITSs) that are designed to interact meaningfully with, and adapt to, the users' input. Different ITSs use

different Natural Language Processing (NLP) techniques in their system. NLP systems may be structural, *i.e.*, focused on grammar and logic, or non-structural, *i.e.*, focused on words and statistics. This article deals with the latter.

Examples of the structural approach include ExtrAns (Extracting Answers from technical texts question-answering system; Molla *et al.*, 2003) which uses minimal logical forms (MLF; that is, the form of first order predicates) to represent both texts and questions and C-Rater (Leacock & Chodorow, 2003) which scores short-answer questions by analyzing the conceptual information of an answer in respect to the given question. Turning to the non-structural approach, AutoTutor (Graesser *et al.*, 2000) uses LSA to analyze the student's input against expected sets of answers and CIRCSIM-Tutor (Kim *et al.*, 1989) uses a word-matching technique to evaluate students' short answers. The systems considered more fully below, iSTART (McNamara *et al.*, 2004) and R-SAT (Magliano *et al.*, 2006) use both word-matching and LSA in assessing quality of students' self-explanation. Topic models (TM) were explored in both systems, but have not yet been integrated.

MAIN FOCUS OF THE CHAPTER

This article presents three non-structural NLP techniques (WM, LSA, and TM) which are currently used

or being explored in reading strategies assessment and training applications, particularly, iSTART and R-SAT.

Word Matching

Word matching is a simple and intuitive way to estimate the nature of an explanation. There are two ways to compare words from the reader's input (either answers or explanations) against benchmarks (collections of words that represent a unit of text or an ideal answer): (1) Literal word matching and (2) Soundex matching.

Literal word matching – Words are compared character by character and if there is a match of sufficient length then we call this a *literal match*. An alternative is to count words that have the same stem (*e.g.*, indexer and indexing) as matching. If a word is short a complete match may be required to reduce the number of false-positives.

Soundex matching – This algorithm compensates for misspellings by mapping similar characters to the same soundex symbol (Christian, 1998). Words are transformed to their soundex code by retaining the first character, dropping the vowels, and then converting other characters into soundex symbols: 1 for *b, p*; 2 for *f, v*; 3 for *c, k, s*; *etc.* Sometimes only one consecutive occurrence of the same symbol is retained. There are many variants of this algorithm designed to reduce the number of false positives (*e.g.*, Philips, 1990). As in literal matching, short words may require a full soundex match while for longer words the first *n* soundex symbols may suffice.

Word-matching is also used in other applications, such as, CIRCSIM-Tutor (Kim *et al.*, 1989) on short-answer questions and Short Essay Grading System (Ventura *et al.*, 2004) on questions with ideal expert answers.

Latent Semantic Analysis (LSA)

Latent Semantic Analysis (LSA; Landauer, Foltz, & Laham, 1998) uses statistical computation to extract and represent the meaning of words. Meanings are represented in terms of their similarity to other words in a large corpus of documents. LSA begins by finding the frequency of terms used and the number of co-occurrences in each document throughout the corpus and then uses a powerful mathematical transformation to find deeper meanings and relations between words.

When measuring the similarity between text-objects, LSA's accuracy improves with the size of the objects, so it provides the most benefit in finding similarity between two documents but as it does not take word order into account, short documents may not receive the full benefit. The details for constructing an LSA corpus matrix are in Landauer & Dumais (1997). Briefly, the steps are: (1) select a corpus; (2) create a term-document-frequency (TDF) matrix; (3) apply Singular Value Decomposition (SVD; Press *et al.*, 1986) to the TDF matrix to decompose it into three matrices ($L \times S \times R$; where *S* is a scaling, matrix). The leftmost matrix (*L*) becomes the LSA matrix of that corpus. The optimal size is usually in the range of 300–400 dimensions. Hence, the LSA matrix dimensions become $N \times D$ where *N* is the number of unique words in the entire corpus and *D* is the optimal dimension (reduced from the total number of documents in the entire corpus).

The similarity of terms (or words) is computed by comparing two rows, each representing a term vector. This is done by taking the cosine of the two term vectors. To find the similarity of sentences or documents, (1) for each document, create a document vector using the sum of the term vectors of all the terms appearing in the document and (2) calculate a cosine between two document vectors. Cosine values range from ± 1 where +1 means highly similar.

To use LSA in the tutoring systems, a set of benchmarks are created and compared with the trainee's input. Examples benchmarks are the current target sentence, previous sentences, and the ideal answer. A high cosine value between the current sentence benchmark and the reader's input would indicate that the reader understood the sentence and was able to paraphrase what was read. To provide appropriate feedback, a number of cosines are computed (one for each benchmark). Various statistical methods, such as discriminant analysis and regression analysis, are used to construct the feedback formula. McNamara *et al.* (2007) describe various ways that LSA can be used to evaluate the reader's explanations: either LSA alone or a combination of LSA with WM. The final conclusion is that a fully-automated (*i.e.*, less hand-crafted benchmarks construction), combined system produces the better results.

There are a number of other intelligent tutoring systems that use LSA in their feedback system, for examples, Summary Street (Steinhart, 2001), Auto-

Tutor (Greasser *et al.*, 2000), and Tutoring System (Lemaire, 1999).

Topic Models

The Topic Models approach (TM; Steyvers & Griffiths, 2007) applies a probabilistic model to find a relationship between terms and documents in terms of topics. A document is considered to be generated probabilistically from a number of topics where each topic consists of a number of terms, each given a probability of selection if that topic is used. By using a TM matrix, the probability that a certain topic was used in the creation of a given document is estimated. If two documents are similar, the estimates of the topics within these documents should be similar. TM is similar to LSA, except that a term-document frequency matrix is factored into two matrices instead of three: one is the probabilities of terms belonging to the topics (the TM matrix), the other the probabilities of topics belonging to the documents. The Topic Modeling Toolbox (Steyvers & Griffiths, 2007) can be used to construct a TM matrix,

To measure the similarity between documents, the Kullback Leibler distance (KL-distance; Steyvers & Griffiths, 2007) is recommended, rather than the cosine measure (which can also be used). Using TM in a tutoring system is similar to using LSA, where a set of benchmarks is defined and the reader's input is compared against each benchmark. The only difference is the use of KL-distance instead of LSA-cosine value. The preliminary results of investigating TM in place of LSA (Boonthum, Levinstein, & McNamara, 2006) indicate that TM is as good as LSA alone (correlation between computerized-scores and human rating scores), but a little bit lower than a combined system using both WM and LSA. This suggests that the TM should be further investigated in combination with WM or LSA or both.

TM is mostly used in document clustering (grouping documents based on relevancy or similar topics; Buntine *et al.*, 2005), data mining (Tuulos & Tirri, 2004), and search engines (Perkiö *et al.*, 2004). A variation on TM by Steyvers & Griffiths (2007), is *Probabilistic Latent Semantic Analysis* (PLSA; Hofmann, 2001) which models each document as generated from a number of hidden topics and each topic has its features defined as the conditional probabilities of word occurrences in that topic.

iSTART and RSAT Applications

iSTART (Interactive Strategy Trainer for Active Reading and Thinking) is a web-based, automated tutor designed to help students become better readers using multi-media technology. It provides adolescent to college-aged students with a program of self-explanation and reading strategy training (McNamara *et al.*, 2004) called Self-Explanation Reading Training, or SERT (see McNamara *et al.*, 2004). iSTART consists of three modules: Introduction (description of SERT and reading strategies), Demonstration (illustration of how these reading strategies can be used), and Practice (hands-on practice of these reading strategies). In the Practice module, students practice using reading strategies by typing self-explanations of sentences. The system evaluates each explanation and then provides appropriate feedback to the student. If the explanation is irrelevant or too short compared to the given sentence and passage, the student is required to add more information. Otherwise, the feedback is based on the level of its overall quality.

The computational challenge is to provide appropriate feedback to the students about their explanations. Doing so requires capturing some sense of both the meaning and quality of their explanation. A combination of word-matching and LSA provided better results (comparing the computerized-score using NLP techniques to the human rating score and having higher correlation between these two sets of scores) than either separately (McNamara, Boonthum, Levinstein, & Millis, 2007).

R-SAT (Reading Strategy Assessment Tool; Maglino *et al.*, 2007) is an automated web-based reading assessment tool designed to measure readers' comprehension and spontaneous use of reading strategies. The R-SAT is similar to the iSTART Practice module in the sense that it presents passages to the reader one sentence at a time and asks for the reader's input. The difference is that, instead of an explanation, R-SAT asks either an indirect ("What are your thoughts regarding your understanding of the sentence in the context of the passage?") or a direct question (*e.g.*, Why did the miller want to marry the girl?) at pre-selected target sentences. The answers to the indirect questions are evaluated on how they are related to the given sentence and passage; the answers to the direct questions are assessed by comparing them to ideal answers.

The problem is to analyze the answers and generate a set of scores for overall comprehension and strategy usage. Ultimately, these scores can be used as a pre-assessment for iSTART allowing the trainer to individualize the iSTART curriculum based on the reader's needs. R-SAT was initially proposed to use word-matching, LSA, and other techniques beyond LSA. However, during the course of development, word-matching was found to produce better results than LSA or in combination with LSA.

FUTURE TRENDS

These three NLP techniques (WM, LSA, and TM) are used in the ongoing research on assessing and improving comprehension skills via reading strategies in the R-SAT and iSTART projects. WM and LSA have been extensively investigated for iSTART and to some extent in R-SAT. The lack of success of LSA compared to the simpler WM in R-SAT is somewhat surprising and may be due to particular features of the algorithms used or to the variety of text genres used in R-SAT. Future work is planned with modified algorithms and substituting genre-specific LSA spaces for the general space now used. In addition TM needs further exploration, especially in its use with small units of text where the recommended Kullback Leibler distance has not proven particularly effective.

CONCLUSION

The purpose of this article is to describe three NLP techniques and how they can be used in assessment tools and intelligent tutoring systems. For iSTART to teach reading strategies effectively, it must be able to deliver valid feedback on the quality of the explanations that a reader produces and therefore the system must understand, at least to some extent, the explanation. Of course, automating natural language understanding has been extremely challenging, especially for non-restrictive content domains like explaining a freely-entered text. Algorithms such as LSA open up a number of possibilities to systems such as iSTART: in essence LSA provides a 'simple' algorithm that allowed tutoring systems to provide appropriate feedback to students (see Landauer *et al.*, 2007). The results presented in Boonthum *et*

al. (2006) show that the topic model similarly offers a wealth of possibilities in natural language processing. For R-SAT to measure a reader's comprehension and reading skills accurately, like iSTART it must also be able to understand, to some extent, what a reader says, especially when he/she is asked to describe their current thoughts. Although LSA is a good candidate, simple word matching against various benchmarks seems adequate to provide satisfactory results especially when aggregated over several explanations (see Magliano *et al.*, 2006). It also demonstrates that a combination of techniques produces better results than using one technique on its own.

KEY TERMS

Intelligent Tutoring System (ITS): Also called Intelligence Computer-Aided Instruction (ICAI), a personal training assistant that captures the subject matter and teaching expertise and individualize the curriculum to meet each learner's needs in order to master the subject matter. Its main goal is to provide benefits of the one-on-one instruction: lessons are conducted at the learner's own pace; practices are interactive so the learner can improve their weaker skills; and real-time question answering clarify learner's doubts or misunderstanding; and an individualized curriculum based on the learner's needs.

Kullback Leibler Distance (KL-distance): A natural distance function from a "true" probability distribution to a "target" probability distribution. It can be interpreted as the expected extra message-length per datum due to using a code based on the wrong (target) distribution compared to using a code based on the true distribution.

Latent Semantic Analysis (LSA): A natural language processing technique that analyses relationships between a set of documents and terms within these documents. LSA was created in 1990 for informa-

tion retrieval and is sometimes called latent semantic indexing (LSI).

LSA Cosine: A measurement of a relation between two vector-units. A unit can be as small as a word or as large as an entire document. It can be computed using the dot-product of two vectors where each vector is a representation of a unit (word, sentence, paragraph, or whole document).

Probabilistic Latent Semantic Analysis (PLSA): A statistical techniques for the analysis of two-mode and co-occurrence data, which has applications in information retrieval and filtering, natural language processing, machine learning from text, and related areas. PLSA evolved from LSA but focuses more on the relationship of topics within documents.

Protocols: Any verbal input that students or readers produce during a session. This can be a set of explanations or answers to direct questions.

Self-Explanation and Reading Strategy Trainer (SERT): Pedagogy uses five strategies to help students become a better reader. The reading strategies include (1) comprehension monitoring, being aware of one's own understanding of the text; (2) paraphrasing, or restating the text in different words; (3) elaboration, using prior knowledge or experiences to understand the text (domain-specific knowledge-based inferences) or using common-sense or logic to understand the text (general knowledge based inferences); (4) predictions, predicting what the text will say next; and (5) bridging, understanding the relation between separate sentences of the text.

Word Matching (WM): A simple way to compare words. Literal match is done by comparing character by character, while Soundex match transforms each word into a Soundex code, similar to phonetic spelling.

Non-Cooperative Facial Biometric Identification Systems

Carlos M. Travieso González

University of Las Palmas de Gran Canaria, Spain

INTRODUCTION

The verification of identity is becoming a crucial factor in our hugely interconnected society. Questions such as “Is she really who she claims to be?”, “Is this person authorized to use this facility?” are routinely being posed in a variety of scenarios ranging from issuing a driver’s license to gaining entry into a country. The necessity for reliable user authentication techniques has increased in the wake of heightened concerns about security and rapid advancements in networking, communication, and mobility. Biometric systems, described as the science in order to recognize an individual based on his or her physical or behavioural traits, is beginning to get acceptance as a legitimate method in order to determine an individual’s identity. Nowadays, biometric systems have been deployed in various commercial, civilian, and forensic applications as a means of establishing identity.

In particular, this work presents a non-cooperative identification system based on facial biometric.

BACKGROUND

How do biological measurements qualify as being biometric? Any human physiological and/or behavioural characteristic can be used as a biometric characteristic as long as it satisfies the following requirements (Jain, Ross & Prabhakar, 2004): universality, distinctiveness, permanence, collectability.

The choice of biometric identifiers has a major impact on the performance of the system. This choice depends greatly on the intended application of the system. Currently, some of the most widely used biometrics identifiers include fingerprints (Jain, Ross &

Prabhakar, 2004, pp. 43-64), hand geometry (Sanchez-Reillo, Sanchez-Avila, Gonzalez-Marcos, 2000), iris (Jain, Ross & Prabhakar, 2004, pp. 103-121), face (Jain, Ross & Prabhakar, 2004, pp. 65-86), etc...

Most biometric systems require co-operation on the part of the users in order to acquire their biometric data. Face identification, however, does not require this condition for its use, although it can be used. This is therefore its principal advantage over other biometric systems. Human face identification is an extensively studied field since the computational cost has not been turned out to be a drawback, due to the increasing importance of this kind of biometric identification in the access security to places such as airports, metros, train and bus stations. The process of facial identification incorporates two significant methods: detection (an individual from among a set) and identification (whether an individual is whom s/he claims to be).

Face detection (Young-Bum Sun, Jin-Tae Kim & Won-Hyung Lee, 2002) involves locating the human face within an image captured by a video camera and taking that face and isolating it from the other objects captured within the image.

Identification is comparing the captured face with other faces that have been saved and stored in a database. The basic underlying identification technology of facial feature identification involves either eigenfeatures (facial metrics) or eigenfaces. Within this type of study a great variety of references can be found (Discrete Cosine Transform (DCT), Karhunen-Loeve (KL) Transform, Independent Component Analysis (ICA), Principal Component Analysis (PCA), etc). The greatest advantage of a facial identification system is its non-cooperative nature as it is a system which can work independently of user co-operation.

FACIAL IDENTIFICATION SYSTEM

This article presents the two principal processes associated with face identification: face detection and face identification. However, there also exist other aspects of facial identification system to be taken into account. In the face detection module the face capturing is shown, just when the camera takes a picture or frame. The image acquisition can be carried out using RGB images, Infrared (IR) images among other formats; recently thermal images are also being used. The choice of the image format depends on its applications, lighting conditions, location (indoor or outdoor system), and the degree of security.

In the face identification module, a database can be found with the user information that must be located; therefore a supervised classification must be carried out. The parametrization submodule extracts the user features, and the classification system generates a model in order to difference our user/users versus the remainder of persons (see figure 1).

Face Detection

The challenges associated with face detection can be attributed to the following factors: Pose, presence or absence of structural components, facial expression, occlusion, image orientation, imaging conditions.

There are many closely related problems with respect to face detection. Face localization aims to determine the image position of a single face; this is a simplified detection problem with the assumption that an input image contains only one face (Lam & Yan, 1994). The goal of facial feature detection is the detection of the presence and location of features, such as eyes, nose,

nostrils, eyebrow, mouth, lips, ears, etc., with the assumption that there is only one face in an image (Zhiwei, & Oiang, 2006). Face recognition or face identification compares an input image against a database and reports a match, if found (Darrell, Gordon, Harville & Woodfill, 2000). The purpose of face authentication is to verify the claim of the individual's identity in an input image (Crowley & Berard, 1997), while face tracking methods continuously estimate the location and possibly the orientation of a face in an image sequence in real time (Darrell, Gordon, Harville, & Woodfill, 2000, Zhiwei, & Qiang, 2006) (see figure 2).

Several face detection systems have been introduced (Ming-Hsuan Yang, David Kriegman & Narendra Ahuja, 2002) (Yang, Ahuja, & Kriegman, 2000). There are many existing techniques to detect faces based on a single image. The techniques for face detection with a single image were classified into three categories.

- Knowledge Based System:** This approach depends on using rules about human facial features to detect faces. Human facial features such as two eyes that are symmetric to each other, a nose and mouth, and other distance features represent this feature set. After detecting features, a verification process is carried out to reduce false detection. This approach is good for frontal images, as is shown in figure 3. The difficulty lies in translating human knowledge into known rules and to detect faces in different poses. Furthermore, the surrounding environment can also pose a problem. For example, changes in light sources can add or remove shadows from a face. Therefore, many variables should be considered when designing a face detection system.

Figure 1. Block diagram for a non-cooperative facial identification

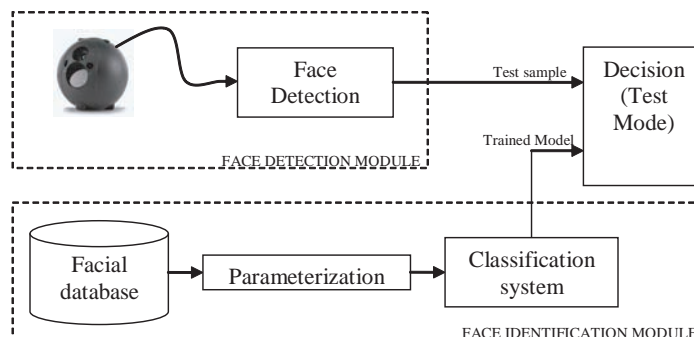

Figure 2. Face detection examples in a motion picture captures

For these reasons, in a non-cooperative system this technique suffers invariability.

- **Image Based System:** In this approach, a pre-defined standard face pattern is used to match with the segments in the image to determine whether they are faces or not. It uses training algorithms to classify regions into face or non-face classes. Image-based techniques depend on multi-resolution window scanning to detect faces, so these techniques have high detection rates but are slower than the feature-based techniques. Eigenfaces (Yang, Ahuja, & Kriegman, 2000) and neural networks (Rowley, Baluja & Kanade, 1998) are examples of image-based techniques. This approach has the advantage of being simple to implement, but it cannot effectively deal with variation in scale, pose and shape (Rein-Lien Hsu & Jain, 2002).
- **Features Based System:** This approach depends on extraction of facial features, which are not affected by variations of lighting conditions, pose, and/or other factors. These methods are classified

according to the extracted features. Feature-based techniques depend on feature derivation and analysis to gain the required knowledge about faces. Features may be skin colour, face shape, or facial features such as eyes, nose, etc.... Feature based methods are preferred for real time systems where the multi-resolution window scanning used by image based methods are not applicable. Human skin colour is an effective feature used to detect faces, because although different people have different skin colours, several studies have shown that the basic difference is based on their intensity rather than their chrominance. Human faces have a special texture that can be used to separate them from different objects (Bojkovic, & Samcovic, 2006). The facial features method depends on detecting features of the face.

Face Identification in Transform Domain Systems

The detected faces always have variable conditions (lighting, expression, rotation, translation, etc), and therefore, images used to train can have some changes with respect to images from face detection. The use of Features or Knowledge Based Systems is a disadvantage due to the wide data variability from variable conditions. Therefore, transform domain systems are a good goal because they group the information and contribute more discrimination to the facial identification.

Transform domain analysis is a commonly used image processing and a parameterization technique. In recent years some work has been done to extract transform domain features for image identification. Li et al. extract Fourier range and angle features to identify the palm-print image (Li, Zhang & Xu, 2002). Lai et al. use holistic Fourier invariant features to recognize the facial image (Lai, Yuen & Feng, 2001). Another spectral

Figure 3. A typical face image used in knowledge based methods

feature generated from singular value decomposition (SVD) is used by some researchers (Chellappa, Wilson & Sirohey, 1995). However, Tian *et al.* indicate that this feature does not contain adequate information for face recognition (Tian, Tan, Wang & Fang, 2003). Hafed and Levine (2001) extract discrete cosine transform (DCT) feature for face recognition. They point out that DCT obtains the near-optimal performance of Karhunen–Loeve (KL) transform in facial information compression. And the performance of DCT is superior to those of discrete Fourier transform (FT) and other conventional transforms. By manually selecting the DCT frequency bands, their recognition method achieves a similar recognition effect to the Eigenface method (M. H. Yang, 2002) which is based on KL transform. Nevertheless, their method cannot provide a rational band selection rule or strategy. Nor can it outperform the classic Eigenface method.

In addition, some extended discrimination methods are proposed. Zhang *et al.* (2002) present a dual Eigenspace method for face recognition. In his work, W. Malina (2001), proposed several new discrimination principles based on the Fisher criterion. Yang uses principal component analysis kernel (PCA) for facial feature extraction and recognition (Bartlett, Movellan & Sejnowski, 2002), while Bartlett *et al.* (2002) apply the independent component analysis (ICA) in face recognition. However, Yang shows that both ICA and PCA kernels need much more computing time than PCA. In addition, when the Euclidean distance is used, there is no significant difference in the classification performance of PCA and ICA (Bartlett, Movellan & Sejnowski, 2002). Jing *et al.* (2003) put forward a classifier combination method for face recognition. This paper does not analyze and compare these extended

discrimination methods, but limits itself to a comparison of major linear discrimination methods including the Eigenface method, the Fisherface method, DLDA and discriminated waveletface.

The KL transform is an optimal transform for removing statistical correlation. Of the discrete transforms, DCT approaches the KL transform (Hu, Worrall, Sadka & Kondo, 2001). In other words, DCT has strong ability to remove correlation and compress images. Furthermore, DCT can be used by fast Fourier transform (FFT), while there is no fast realization algorithm for KL transform. Therefore, our approach sufficiently uses these favourable properties of DCT.

The following table shows different systems based on different methods of face recognition with their corresponding recognition rates. The databases used are ORL [ORL Database], Yale [Yale Database], AR-Face [AR Database] and FERET [FERET Database].

FUTURE TRENDS

Recently, numerous methods that combine several facial features have been proposed to locate or detect faces. Most of them use global features such as skin colour, size, and shape to find face candidates, and then verify these candidates using different local parameterization methods. The challenge is to achieve invariability of the captured images from the conditions (light, shapes ...) and positional changes (rotations, scales ...). The creation and development of new methods based on transform domain system will provide robust characteristics for achieving this invariability.

With respect to facial identification, 3D techniques can be used for the purpose in this system, but the

Figure 4. Face samples with different conditions (lighting and rotation)

computational cost is a major disadvantage for real time applications. Facial rebuilding with 3D techniques can obtain more information and any features can be extracted. Moreover, this system retains the non-cooperation quality. In the future, the use of the multi-modal systems with other biometric characteristics will generate a stronger and robust system.

CONCLUSION

Face recognition is a challenging and interesting problem. However, it can also be regarded as part of the wider attempt to solve one of the greatest challenges to computer vision, that of object recognition. In particular, facial identification is becoming a very important biometric system in the battle to reduce global terrorism. Much research has already been carried out in this field, and bearing in mind the threat to security which the world is currently facing, there will undoubtedly be many more publications on facial identification in the future.

KEY TERMS

Biometric System: This is a system which identifies persons from physical or behavioral characteristics. These characteristics are intrinsic to the individuals.

Face Detection: The act of detecting a face from a frame or an image.

Face Identification: This is a system which creates a model from facial features in order to recognize persons.

Independent Component Analysis (ICA): A computational method for separating a multivariate signal into additive subcomponents supposing the mutual statistical independence of the non-Gaussian source signals.

Multi-Modal System: Use of different biometric system in order to identify or verify persons.

Non-Cooperative Identification System: This is a system for identification which does not require the collaboration of a user in order to operate. The information for identification is obtained with the permission of the user.

Supervised Classification: Classification system that generates a model using training samples, and it uses that model to establish an evaluation or test with other samples.

Transform Domain System: This is a change from visible range to another different range, which transforms the information, providing other properties in this domain.

Nonlinear Techniques for Signals Characterization

Jesús Bernardino Alonso Hernández

University of Las Palmas de Gran Canaria, Spain

Patricia Henríquez Rodríguez

University of Las Palmas de Gran Canaria, Spain

INTRODUCTION

The field of nonlinear **signal characterization** and nonlinear signal processing has attracted a growing number of researchers in the past three decades. This comes from the fact that linear techniques have some limitations in certain areas of signal processing. Numerous nonlinear techniques have been introduced to complement the classical linear methods and as an alternative when the assumption of linearity is inappropriate. Two of these techniques are higher order statistics (HOS) and nonlinear dynamics theory (chaos). They have been widely applied to time series characterization and analysis in several fields, especially in biomedical signals.

Both HOS and chaos techniques have had a similar evolution. They were first studied around 1900: the method of moments (related to HOS) was developed by Pearson and in 1890 Henri Poincaré found sensitive dependence on initial conditions (a symptom of chaos) in a particular case of the three-body problem. Both approaches were replaced by linear techniques until around 1960, when Lorenz rediscovered by coincidence a chaotic system while he was studying the behaviour of air masses. Meanwhile, a group of statisticians at the University of California began to explore the use of HOS techniques again.

However, these techniques were ignored until 1980 when Mendel (Mendel, 1991) developed system identification techniques based on HOS and Ruelle (Ruelle, 1979), Packard (Packard, 1980), Takens (Takens, 1981) and Casdagli (Casdagli, 1989) set the methods to model nonlinear time series through chaos theory. But it is only recently that the application of HOS and chaos in time series has been feasible thanks to higher computation capacity of computers and Digital Signal Processing (DSP) technology.

The present article presents the state of the art of two nonlinear techniques applied to time series analysis: higher order statistics and chaos theory. Some measurements based on HOS and chaos techniques will be described and the way in which these measurements characterize different behaviours of a signal will be analyzed. The application of nonlinear measurements permits more realistic characterization of signals and therefore it is an advance in automatic systems development.

BACKGROUND

In digital signal processing, **estimators** are used in order to characterize signals and systems. These estimators are usually obtained using linear techniques. Their mathematical simplicity and the existence of a unifying linear systems theory made their computation easy. Furthermore, linear processing techniques offer satisfactory performance for a variety of applications.

However, linear models and techniques cannot solve issues such as nonlinearities due to noise, to the production system of the signal, system nonlinearities in digital signal acquisition, transmission and perception, nonlinearities introduced by the processing method and nonlinear dynamics behaviour. Therefore, the application of linear processing techniques leads to less realistic characterization of certain systems and signals. As a result of the shortcomings of linear techniques, analysis procedures are being revised and nonlinear techniques are being applied in computing **estimators** and models and in **signal characterization** to increase the possibilities of digital signal processing.

HOS is a field of statistical signal processing which has become very popular in the last 25 years. To date almost all digital signal processing have been based

on second order statistics (autocorrelation function, power spectrum). HOS use extra information which can be used to get better estimates of noisy situation and nonlinearities.

Chaos theory (nonlinear dynamical theory) is a long-term unpredictable behaviour in a nonlinear dynamic system caused by sensitive on initial conditions. Therefore, irregularities in a signal can be produced not only by random external input but also by chaotic behaviour.

Both nonlinear techniques have been used in signals characterization and numerous automatic classification systems have been developed using HOS and chaos features in many fields. Texture classification (Coroyer, Declercq, Duvaut, 1997), seismic event prediction (Van Zyl, 2001), fault diagnosis in machine condition monitoring through vibration signals (Samanta, Al-Balushi, & Al-Araimi, 2006), (Wang & Lin, 2003) and economy (Hommes & Manzan, 2006) are some examples.

Their application in biomedical signals is especially important. Nonlinear features have proven to be useful in voice, electrocardiogram (ECG) and electroencephalogram (EEG) signals characterization. Automatic classification systems between pathological and healthy voices have been implemented using nonlinear features (Alonso, de León, Alonso, Ferrer, 2001) (Alonso, Díaz-de-María, Travieso, Ferrer, 2005). Nonlinear characteristics have been used in the detection of electrocardiographic changes through ECG signal (Ubeyli & Guler, 2004), in the evaluation of neurological diseases using EEG signal (Gulera, Ubeyli & Guler, 2005), (Kannathal, Lim Choo Min, Rajendra Acharya & Sadasivan, 2005) and in diagnosis of phonocardiogram (Shen, Shen, 1997).

NONLINEAR METHODS: CHAOS THEORY AND HIGHER ORDER STATISTICS APPLIED TO TIME SERIES

Higher Order Statistics

Higher Order Statistics, known as cumulants and their Fourier transform, known as polyspectra are extensions of second-order measures (such as the autocorrelation function and power spectrum). Some advantages of HOS over second-order statistics are:

1. HOS give amplitude and phase information in the spectral domain, whereas second order statistics only give amplitude information (Mendel, 1991) (Nikias & Petropulu, 1993). Therefore, non-minimum phase signals and certain types of phase coupling (associated with nonlinearities) cannot be correctly identified by second-order statistics.
2. HOS are blind to Gaussian processes whereas correlation is not (Mendel, 1991). Therefore, cumulants can be used in determining Gaussian noise levels in a signal, separating non-Gaussian signals from Gaussian noise, in harmonics components estimation or in increasing signal to noise ratio (SNR) when signals are contaminated with Gaussian noise.

The second-order measures work properly if the signal has a Gaussian probability density function, but many real-life signals are non-Gaussian. Therefore, HOS are a powerful tool to work with non-Gaussian and nonlinear processes.

Next, some higher order statistics measurements are shown and their usefulness in characterizing certain nonlinear phenomena is explained.

Third Order Moment: Skewness

Skewness is a third order moment and a measure of the asymmetry in a probability distribution. This measurement enables us to discriminate among different kind of data distribution as its value varies according to the asymmetry of a distribution. The skewness of a Normal distribution is zero (data symmetric about the mean), positive skewness corresponds to a distribution with a right tail longer and negative skewness to a distribution with a left tail longer.

In most cases normal distribution is assumed, but data points are not usually perfectly symmetric. Skewness reflects positive or negative deviations from the mean and gives more realistic characterization of a data set.

Fourth Order Moment: Kurtosis

Kurtosis is a fourth order moment and a measure of whether the data in a probability distribution are peaked

or flat relative to a Normal distribution. Kurtosis is a measure of the data concentration about the mean, higher kurtosis means more of the variance is due to infrequent extreme deviations.

Higher Order Cumulants

Higher order moments are natural generalization of autocorrelation, while cumulant (Mendel, 1991) are nonlinear combinations of moments. The second order cumulant is the autocorrelation function. Higher order cumulants can be seen as a measure of gaussianity of a random process because cumulants higher than second order are zero in a gaussian process.

Bispectrum

Bispectrum is the Fourier transform of the third order cumulant. The bispectrum of a stationary Gaussian process with zero media are equal to zero. The bispectrum of a signal plus Gaussian noise is the same as that of the signal, whereas the power spectrum of a signal plus Gaussian noise is very different from the power spectrum of the signal alone.

Therefore, through bispectrum Gaussian noise can be separated from non-Gaussian noise and signal-to-noise ratios can be improved.

On the other hand, quadratic phase coupling can be detected and no minimum phase systems can be identified with the bispectrum.

Bicoherence

Closely related to the bispectrum is the third-order coherence measure, the bicoherence. Bicoherence is the bispectrum normalized.

Bicoherence is bounded between 0 and 1 values and it is used to detect quadratic phase coupling due to second order alinearities. A phase coupling between a linear combination of the frequency components ω_1 and ω_2 exists if the bicoherence has a value equal to one for a pair of frequencies (ω_1, ω_2) .

Chaos Theory

The Chaos theory helps us to understand and interpret the observations from complex deterministic dynamical systems and it can be used to predict and control time series (Kantz & Schreiber, 1997). Until the appear-

ance of the chaos theory all irregular behaviour was interpreted as a stochastic behaviour and therefore unpredictable. Thanks to the chaos theory this is not necessarily true. For example, stochastic and chaotic systems have rich broadband power spectra and varying phase spectra. So, in order to distinguish between stochastic and chaotic systems the chaos theory is a powerful new tool.

A deterministic dynamical system describes the time evolution of a system in some phase space $\Gamma \in \mathbb{R}^m$ (m dimensional vectorial space), where a state is specified by a vector $\bar{x} \in \mathbb{R}^m$. This evolution can be expressed by ordinary differential equations (Kantz & Schreiber, 1997):

$$\frac{d}{dt} \bar{x}(t) = f(t, \bar{x}(t)), t \in \mathbb{R}$$

or in discrete time $t = n\Delta t$ by maps:

$$\bar{x}_{n+1} = F(\bar{x}_n), n \in \mathbb{Z}$$

A sequence of points $(\bar{x}_n$ or $\bar{x}(t))$ that solve the equations of the system are called trajectories. The initial conditions are \bar{x}_0 or $\bar{x}(0)$, respectively. The region of the phase space in which all trajectories originated in a range of initial conditions converges after a transition time is called attractor. An example of a chaotic attractor from the Colpitts oscillator (Kennedy, 1994) is illustrated in Figure 1.

Most of the time we need to characterize nonlinear systems for which equations and models are unknown. However, some measurements of the system are known.

Figure 1. Attractor from Colpitts oscillator

There exist some techniques to obtain the phase space and the attractor from the output signal (**embedding techniques**). Thus, certain quantities such as Lyapunov exponents, **correlation dimension** and Kolmogorov-Sinai entropy are obtained from the attractor. These quantities provide measurements of the nonlinearity degree of the system. These measurements are invariant under smooth transformations and thus independent of the embedding procedure.

Embedding Techniques

Takens' embedding theorem (Takens, 1981) states that an embedding exists if the dimension (m) of the reconstructed phase space is such that $m > 2D + 1$ (D is the attractor dimension). There exist two main methods to reconstruct the attractor from a time series: the **method of delays** (Kantz & Schreiber, 1997) and principal component analysis (Broomhead & King, 1986). The former method is the most popular: a delay reconstruction in m dimensions is formed by the vectors s_n given as (Kantz & Schreiber, 1997),

$$s_n = [s(n), s(n-T), \dots, s(n-(m-1)T)]$$

where $s(n)$ is the scalar signal measured, m is the **embedding dimension** of the reconstructed phase space and T is the **time delay**.

Takens' theorem is strictly an existence theorem and does not suggest how to find the embedding dimension (m) and the time delay (T). The first zero of autocorrelation function or when it decays $\frac{1}{e}$ has been suggested as a first order **estimator** of T . The first minimum of mutual information function (Fraser & Swinney, 1986) is another estimator of T that takes into account nonlinear correlations.

The false neighbours method (Kennel, Brown & Abarbanel, 1992) and the false strands method are proposed methods to estimate the embedding dimension (m). The latter is an improvement of the false neighbours method.

Chaotic Measurements

In the following paragraphs some chaotic measurements will be described.

Lyapunov Exponents

Lyapunov exponents characterize the rate of separation of two points in phase space initially separated by a small distance. There exist as many Lyapunov exponents as m (dimension of the phase space). The maximal Lyapunov exponent (MLE) is the largest one and determines the predictability of a dynamical system. A positive MLE means divergence of nearby trajectories, i.e. chaos. For a mathematical description we refer the reader to (Kantz & Schreiber, 1997). Several algorithms to compute Lyapunov exponents from a time series have been implemented (Wolf et. al, 1985), (Rosenstein, Collins, De Luca, 1993), (Kantz, 1994), (Sprott, 2003).

MLE is useful to characterize different kinds of behaviour in a signal or system. A negative MLE is an indicator of a stable fixed point (a dissipative or non-conservative system), a positive MLE is an indicator of irregular (chaotic) behaviour, a zero MLE is an indicator of a conservative system (such as a harmonic oscillator) and an infinite MLE is an indicator of noise.

Kolmogorov-Sinai Entropy

Kolmogorov-Sinai (KS) entropy quantifies the loss of information as a system evolves and it is another measurement related to the unpredictability of a system. In a regular and predictable system, $H_{KS} = 0$, i.e. nearby points are closely grouped in some other small region of phase space and there is no change in information. In a random process $H_{KS} = \infty$ due to the fact that all phase space regions become possible after a short time. In chaotic systems $0 < H_{KS} < \infty$ indicates that nearby points in the phase space diverge exponentially. Therefore, according to KS entropy values different types of systems can be characterized: regular, chaotic and noise systems.

Correlation Dimension

Correlation dimension (Grassberger & Procaccia, 1983) quantifies the complexity of the reconstructed attractor. It is a geometric measurement of sensitive dependence on initial conditions because in chaotic motion the attractor usually shows a very complicated and fractal geometry. In a chaotic deterministic system the

correlation dimension yields to a finite value, whereas in a random process it does not converge to a value. A maximum likelihood **estimator** to obtain optimal values of correlation dimension is the Takens-Theiler estimator (Theiler, 1988).

Correlation dimension allows us to identify a random process from a chaotic motion. A non-integer (fractal) value of the correlation dimension is usually a symptom of chaos, whereas a integer value is a symptom of a regular behaviour. Furthermore, the correlation dimension is an estimation of the number of degrees of freedom of a system.

FUTURE TRENDS

In automatic recognition systems it is necessary to characterize data sequences and objects (voice, sounds, faces, hands, etc.) in order to achieve a well described features space. Having differential features will later lead to a successful classification process.

However, the task of finding differential features is not always easy. Nonlinear techniques are novel resources to characterize time series and overcome certain previous problems of linear techniques. Proof of this is the development of several automatic classification systems using nonlinear features such as (Alonso, de León, Alonso, Ferrer, 2001) (Alonso, Díaz-de-María, Travieso, Ferrer, 2005), (Ubeyli & Guler, 2004), (Gulera, Ubeylib & Guler, 2005).

CONCLUSION

In this article we have shown the state of the art in two recent nonlinear techniques: Higher order statistics and the chaos theory. The main point is the fact that many signals in real life cannot be adequately modelled by linear approximation alone. Recently, the development of packages to compute chaotic (TISEAN package, Hegger, Kantz & Schreiber, 1999) and HOS (HOSA toolbox for Matlab) measures from data sets has made the application of these techniques to data sets feasible.

Thanks to these techniques it is now possible to extract new characteristics previously ignored by linear analysis. Therefore the use of nonlinear techniques

leads to more realistic characterization of signals and systems.

These new approaches to signal analysis and characterization provide new tools for the better characterization of signals and as a previous step in order to create new, more accurate and powerful automatic systems in patter recognition systems such as voice and facial recognition.

KEY TERMS

Attractor: A region in the phase space to which all trajectories converge after a transition time. It is the long term behaviour of a dynamical system.

Bicoherence: It is a normalised version of the bispectrum. The bicoherence takes values bounded

between 0 and 1, which make it a convenient measure for quantifying the phase coupling in a signal.

Chaos: Long-term unpredictable behaviour caused by sensitive dependence on initial conditions.

Cumulants: The k th order cumulant is a function of the moments of orders up to and including k .

HOS: Higher order statistics is a field of statistical signal processing that uses more information than autocorrelation functions and spectrum. It uses moments, cumulants and polyspectra. They can be used to get better estimates of parameters in noisy situations, or to detect nonlinearities in the signals.

Kolmogorov-Sinai Entropy: Measurement of information loss per unit of time in phase space.

Lyapunov Exponents: Quantity that characterizes the rate of separation of infinitesimally close trajectories in a dynamical system. The maximal Lyapunov exponent (MLE) determines the predictability of a dynamical system. A positive MLE means a chaotic system.

Polyspectra: The Fourier transform of cumulants. The second order polyspectra is the power spectrum. Most HOS work on polyspectra focusses attention on the bispectrum and the trispectrum.

Reconstructed Phase Space: Phase space obtained from a time series through embedding techniques such as principal component analysis or the method of delays.

Ontologies and Processing Patterns for Microarrays

Mónica Miguélez Rico

University of A Coruña, Spain

José Antonio Seoane Fernández

University of A Coruña, Spain

Julián Dorado de la Calle

University of A Coruña, Spain

INTRODUCTION

The researchers currently have a new tool for dealing with the solution of biomedical problems: the Microarrays. These devices support the study and the acquisition of information related to many genes at the same time by means of a unique experiment, providing multiple potential applications such as mutation detection of microorganism identification.

Some of the problems that exist when working with this type of technologies are the high number of data and the complex technical nomenclature to be dealt with. These facts imply the need of using several standards and ontologies when performing this type of experiments.

BACKGROUND

The microarrays have been a key element in the biotechnological revolution of the last years; however new problems regarding both, data handling and statistics analysis, have arisen due to the vast volume of information and to the structure of the data used.

The main concern lies in the vast amount of data to be stored, processed and analysed. Besides, as the microarrays are a new technique, most of the methods, protocols and standards are still being defined.

The fact of dealing with such amount of unstructured information leads to believe that is quite difficult for the descriptors of the stored concepts or their units to be the same at the different data bases where it is accessed. In order to support the vocabulary unification task, the ontologies (Chandrasekaran, 1999) enable

a hierarchical definition of concepts for framing the schemas of the accessed data bases. There are fully established ontologies also quite used as the UMLS medical vocabulary (UMLS, 2006), that has information about symptoms and illnesses, or the GO (Gene Ontology) genomic ontology (Gene Ontology, 2006), regarding information about the function and the expression location of the different human genes.

Once the use of ontologies has been established, they are also quite useful for searching hidden relationships among data. Consultations with SQL-type (Structured Query Language) (Beaulieu, 2005) query languages may be performed in an ontology and translated to query languages owning to each underlying data base. In this way, by the use of the ontology, it could be known that the presence of fever is a symptom and which are the illnesses that present fever as a symptom.

Currently, there are special data formats in medicine science as the DICOM standard (Oosterwijk, 2001) for storage and transfer of the increasing amount of medical images that support new imaging modalities. Nevertheless, the typical biomedical images, as the microarrays or the DNA gels, are not currently considered at DICOM, although their future integration is foreseeable in incoming revisions, as the clinical test based on these techniques might be increasingly used in routine medical practice. At the moment, however, the management of this type of images is quite sensitive.

MAIN FOCUS OF THE CHAPTER

This paper presents a description of the most important standards and ontologies for working with microarrays

experiments; it also tackles the integration options of some of these ontologies and standards into an information system for managing microarrays.

The first standardisation initiatives appeared in 1998. They were more or less isolated initiatives where three standardisation areas could be distinguished: hardware, fixed material and procedures for analysis and storage of studies information. Several organisations as the MGED Normalization Working Group (MGED Data, 2006) were created for the standardisation of the information. The MGED (Microarray Gene Expression Data) Society is an international organisation devoted to the standardisation and to the exchange of information related to microarrays experiments. Other organisations to be mentioned are the OMG (Object Management Group) (OMG, 2006) or the UCL/HGNC (Human Gene Nomenclature) (HGNC, 2006).

As far as terminologies, vocabularies, nomenclatures and ontologies is concerned, it should be highlighted the MGED Ontology (MGED OWG, 2006), which describes the experiments and the gene expression data, or the GO (Gen Ontology Consortium) (Gene Ontology, 2006), which provides controlled vocabularies for describing the molecular function, the biological process and the cellular components of the gene products. Also the UCL/HGNC (Human Gene Nomenclature) (HGNC, 2006), the TaO (TAMBIS Ontology) (TaO, 2006), the

RiboWeb (RiboWeb, 2001) or the EcoCyc (EcoCyc, 2005) should be mentioned.

Regarding the data exchange standards in the microarrays field, the MicroArray and Gene Expression Markup Language (MAGE-ML) (MAGE-ML, 2006) is language designed for describing and communicating information among microarrays experiments.

Other data exchange standards are the Bioinformatics Sequence Markup Language (BSML) (BSML, 2006), the Gene Expression Markup Language (GeneXML) (NCGR, 2006) or the Genome Annotation Markup Elements (GAME) (Bioxml, 2006).

The MGED Group is the standardisation organisation that presents the wider scope regarding the microarrays field and presented in November 2000 the standard **MIAME (Minimum Information About a Microarray Experiment)** (MIAME, 2006). This acronym describe the minimal information regarding microarrays that, either should be stored into a data base (from now, DD.BB) used as a public repository, or that should be stored for enabling the non ambiguous interpretation of the experiments results and for repeating such experiments.

After defining the information that is going to be stored (MIAME), there should be a model of objects (UML) for describing, not only how the data of these experiments should be expressed, but also the mecha-

Figure 1. MGED ontology

nisms for their exchange, bearing always in mind the MIAME guides. This is precisely what the **MAGE-OM (MicroArray and Gene Experiment Object Model)** (MAGE-OM, 2006) standard defines.

This model of objects has been developed for being independently used from the implementation chosen and, in this way, it can be used as a map for data structures in platforms such as Java, Perl or C++. The model has been currently translated to a set of relational tables divided in packages, according to the natural separation of the gene expression data into cases and objects.

In this point, and by the use of standards already described, the microarrays experiments data to be stored and their model of objects are both defined. A language for the data exchange is therefore needed, as the **MAGE-ML (MicroArray Gene Expression Markup Language)** (MAGE-ML, 2006).

It is a XML (XML, 2006) formal language directly derived from the MAGE-OM object model. This language has been designed for describing and communicating the information of such type of elements and it can be used for describing microarrays-related items such the designs, information about the fabrication or the structure of experiments.

A tool named as **MAGE-stk (MAGE Software Toolkit)** has been developed in order to simplify the use of the MAGE-OM standard. This tool is based on an Open Source package collection that implements the MAGE model of objects (MAGE-OM) in several programming languages. It makes the reading of the MAGE-ML easier; this tool also simplifies the MAGE-ML writing from MAGE-OM and it provides methods for the fully maintenance, as well as actualisation, of MAGE-OM.

Once the standards needed for working with microarrays technology have been defined, the following step is the description and the use of several ontologies that might enable, as it was mentioned before, the unification of the different vocabularies used.

The **MGED Ontology (MO)** is one of the most important ontologies when working with microarrays and, particularly, when using certain previously mentioned standards. The main goal of this ontology is to provide standard terms for the notation of experiments with microarrays; such terms not only will serve for structuring questions related to the elements of the experiments, but also they might be used for unambiguously describing how the experiments have been done.

As the ontology-encoded terms will be eventually placed in MAGE-ML documents, the efforts of both, MAGE and the working group, should be coordinated at the points where they superimpose, for the ontology classes and the MAGE classes to have the same names and relationships.

The ontology has been conceived for continuously growing and therefore fulfilling the requirements of descriptive terms related to emerging applications of microarrays. Besides, the use of ontologies for software programming should be fixed, in order to avoid constant revisions of the programming for searching changes in vocabularies and relationships. The fulfilment of such objectives is achieved by establishing the central MGED ontology, a nucleus at the MGED ontology that will remain constant. The extended MGED ontology is a second ontology layer that contains all the additional terms that might be considered (see Figure 1).

The central MGED ontology has been developed for working with the MAGE 1.0 schema, and it is restricted to MAGE-OM v1.1. The extended MGED ontology increases the ontology nucleus with terms that are out of reach of MAGE v1.1.

The **Gen Ontology (GO)** is other ontology that should be considered when working with microarrays. The Gen Ontology Project implies a collaborative effort in order to fulfil the needs of consistent descriptors for genetic products in different DD.BB. The project started in 1998 as collaboration among three DD.BB. related to models of organisms: FlyBase, Saccharomyces Genome Database (SGD) and the Mouse Genome Database (MGD). Since then, the GO consortium has grown and includes many more DD.BB., as some of the world biggest repositories for plants, animals and microbial genomes.

The GO project has developed three controlled and structured ontologies/vocabularies: biological processes, molecular functions and cellular components. In this way, a given gene can be located in one or more *cellular components*, the *biological processes* where it is active can be checked and the *molecular functions* represented by that gene at those processes can be visualised. For instance, the 'cytochrome c' gene can be described by the *molecular function* term 'oxidoreducta activity', by the *biological process* terms 'oxidate phosphorylation' and 'death cell induction' and by the *cellular component* terms 'mitochondrial matrix' and 'mitochondrial membrane'.

ESSENTIAL CHARACTERISTICS OF AN INFORMATION SYSTEM FOR MICROARRAYS MANAGEMENT

This type of system needs an architecture of data integration for easily store the vast amount of information generated by the experiments with microarrays; In order to achieve this, the architecture should provide the users with assistants and contextual support for handling the information. On the other hand, a Web architecture, by means of an Internet connection, will enable the access and the management of the information from any place at any time.

For the ontology information to be always actualised and available for the users, the architecture should provide an integrated access to several ontology servers. In order to achieve this, it should be advisable to use Web Services in cases as the access to the Gen Ontology (GO) or to the Biological Imaging Methods (FBbi); alternatively, Internet access should be used in MGED Ontology access. Besides, for the users to introduce data and consult the stored information more easily, the system should have an interface that might show a list of ontology terms and values; in this way, this list would enable ontology consultations that might include all the meanings of a given concept.

As the proposed system has to support the information exchange among the different researchers, this type of architecture should use the existing standards related to data storage (MIAME) and to information exchange (MAGE-OM y MAGE-ML). In the first case, the system should have to implement a DD.BB. whose fields fulfil the MIAME standard; in the second case, the system will use the MAGE-OM object model for enabling the generation of the MAGE-ML information exchange file by the users whenever they might require it.

Lastly, it should be also advisable that the users could continue using the existing applications, to which they are used to, and that have been developed by experts on the subject usually using the R language. Due to that reason, the system should have such applications available for the users. In order to achieve this, it is proposed an approach based in the use of Web services by the architecture.

This architecture is being currently developed by the RNASA/IMEDIR lab group from the University of A Coruña.

CONCLUSION

Nowadays there are several tools that enable the analysis of microarrays imaging; however, as they are software specifically designed for each array type, they do not allow wide options and they, not only require to be installed in the user machine, but also its installation is restricted to a few operative systems.

Regarding data processing, there are several projects that include packages for performing microarrays imaging processings as normalisation or clustering; however, some of these packages need to download the different processing tools that they contain in order to use them.

Lastly, there are several types of public DD.BB. for storing the information of this type of experiments by the use of Web formularies. As there are also some stand-alone tools that store the data into a DD.BB. created in the machine of the user, this machine should have a DD.BB. manager installed.

Nevertheless, no systems have been found to perform the different steps without needing to install software or to quit the system.

The new systems of this area should allow the data storage into a MIAME standard DD.BB. with the option of performing the image analysis of the different microarrays experiments and keeping the analysis results into de system DD.BB. The systems should also provide several processing types using R language in order to perform data analysis and subsequent experiment conclusions. The data model of the system should use MAGE-OM standard and then offer the resulting experiment MAGE-ML file to the user.

KEY TERMS

MAGE-ML: *Microarray Gene Expression Markup Language*. Formal language designed for describing and communicating the experiment-based microarrays information.

MAGE-OM: *MicroArray and Gene Experiment Object Model*. Standard that defines the model of objects for the gene expression-based experiments.

MAGE-stk: MAGE Software Toolkit. Open Source Package collection that implements the MAGE (MAGE-OM) model of objects in several programming languages.

MIAME: *Minimum Information About a Microarray Experiment*. Standard that indicates the minimal information needed for microarrays experiments.

MicroArrays: A technology using a high-density array of nucleic acids, protein, or tissue for simultaneously examining complex biological interactions which are identified by specific location on a slide array. A scanning microscope detects the bound, labelled sample and measures the visualized probe to ascertain the activity of the genes of interest in genotyping, cellular studies, and expression analysis.

Ontology: In computer science this term refers to the attempt of formulate an exhaustive and rigorous conceptual schema into a given domain, with the aim of making communication and information sharing among systems easier.

R: Language and programming environment for graphic and statistical analysis.

Ontologies for Education and Learning Design

Manuel Lama

INTRODUCTION

In the last years, the growing of the Internet have opened the door to new ways of learning and education methodologies. Furthermore, the appearance of different tools and applications has increased the need for interoperable as well as reusable learning contents, teaching resources and educational tools (Wiley, 2000). Driven by this new environment, several metadata specifications describing learning resources, such as IEEE LOM (LTCS, 2002) or Dublin Core (DCMI, 2004), and learning design processes (Rawlings et al., 2002) have appeared. In this context, the term learning design is used to describe the method that enables learners to achieve learning objectives after a set of activities are carried out using the resources of an environment. From the proposed specifications, the IMS (IMS, 2003) has emerged as the de facto standard that facilitates the representation of any learning design that can be based on a wide range of pedagogical techniques.

The metadata specifications are useful solutions to describe educational resources in order to favour the interoperability and reuse between learning software platforms. However, the majority of the metadata standards are just focused on determining the vocabulary to represent the different aspects of the learning process, while the meaning of the metadata elements is usually described in natural language. Although this description is easy to understand for the learning participants, it is not appropriate for software programs designed to process the metadata. To solve this issue, ontologies (Gómez-Pérez, Fernández-López, and Corcho, 2004) could be used to describe formally and explicitly the structure and meaning of the metadata elements; that is, an ontology would semantically describe the metadata concepts. Furthermore, both metadata and ontologies emphasize that its description must be shared (or standardized) for a given community.

In this paper, we present a short review of the main ontologies developed in last years in the Education field, focusing on the use that authors have given to the ontologies. As we will show, ontologies solve issues related with the inconsistencies of using natural language descriptions and with the consensus for managing the semantics of a given specification.

ONTOLOGIES IN EDUCATION

In the educational domain a number of ontologies have been developed for authors. Thus ontologies have been developed to describe the learning contents of technical documents and formalize the semantics of learning objects; model the elements required for the design, analysis, and evaluation of the interaction between learners in computer supported cooperative learning; and describe the learning design associated to a unit of learning in which the learning flow is explicitly declared.

Ontologies in Learning Contents and Metadata

The main purpose of these ontologies is to describe the contents or features of documents in order to favor its indexing and retrieval from applications. Thus Kabel, Wielinga, and Hoog (1999) develop three ontologies that annotate technical documents from a given domain: these documents are converted in a large collection of information elements described by a number of attributes to which values are assigned from the ontologies. These attributes are referred to the subject matter in the application domain, structural and representational properties (paragraphs, sections, etc.) and the potential instructional roles of the information elements. Following this approach the ontologies represent the

semantics of the documents, enabling its indexing and retrieving from databases.

Other interesting ontology in this field is proposed by Brase, Painter and Nejd (2004). Using an ontology language as TRIPLE, this ontology describes the semantics of the LOM specification, adding formal axioms and rules to the metadata representation of the standard. With this formal description the semantics of the LOM specification is not changed, but it helps to define the constraints on LOM fields, making clear the meaning and use of these LOM fields, resulting in easier exchange of LOM metadata between different applications and contexts.

Ontologies in Collaborative Learning Environments

These ontologies are used to model the interaction between the learning actors (typically teachers and students) in collaborative environments. Thus Inaba et al. (2001) present an ontology a collaborative learning ontology that facilitates the design, analysis, and evaluation of a collaborative learning session. This ontology describes the concepts of several well-established learning theories, defining the semantics of what learning goal concept is and connecting this concept with the theories which are formulated in a taxonomy. In this work, authors have used the ontology to facilitate users the design and execution of the instructional process in a collaborative environment (Barros, Verdejo, Read, & Mizoguchi, 2002).

Ontologies in Learning Design

These ontologies focus on the semantic description of the learning design modelling which defines the learning flow of the activities to be carried out by teachers and students. The ontologies developed in this field are based on the IMS Learning Design (IMS LD) specification which has risen as a de facto standard for defining learning designs. This specification has: (1) a well-founded conceptual model that declares the vocabulary and the functional relations between the concepts of the learning design; (2) an information model that describes in an informal (natural language) way the semantics of every concept and relation introduced in the conceptual model; and (3) a behavioural model that specifies the constraints imposed to the software system when a given learning design is executed in

runtime. In other words, the behavioural model defines the semantics of the IMS LD specification during the execution phase. Figure 1 depicts the main concepts of the IMS LD specification.

Knight, Gasevic and Richards (2006) present a general framework whose purpose is to save the gap between learning designs and the learning objects used in them. For achieving this, the framework considers the development of three ontologies that describe the learning design, the learning objects and the context in which these objects are used. LOCO is the ontology, defined in the language OWL (Dean & Schreiber, 2004), that deals with the description of learning designs. It represents the semantics specified in IMS LD and, particularly, in its conceptual model, which means that LOCO integrates the concepts and relations defined in the conceptual and information models of the IMS

Figure 1. Main concepts of the IMS Learning Design specification (Amorim et al., 2006)

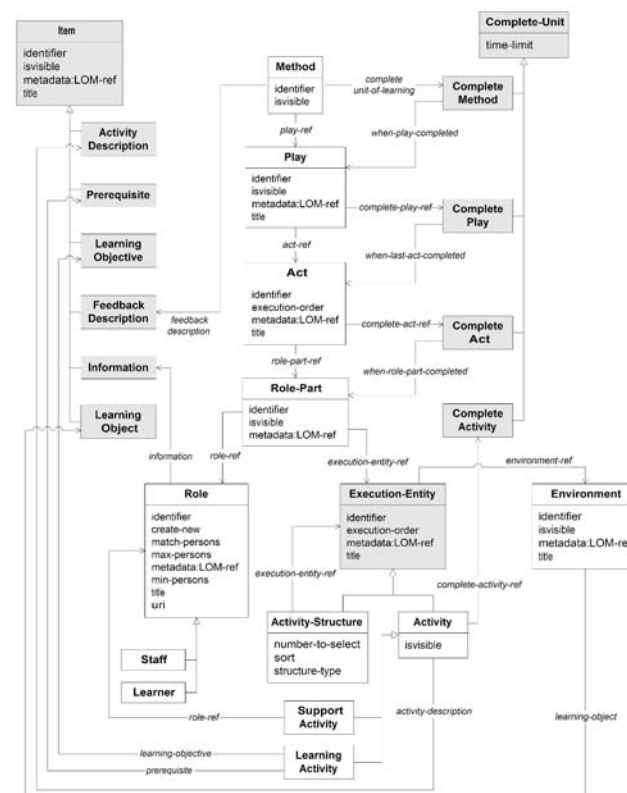

Table 1. Examples of axioms that constrain the semantics of the IMS LD concepts

| | | |
|--------------------|---------------------------|--|
| Design Axiom 1 | IMS LD Specification | Page 38 (item 0.2.2): “The time limit specifies that it is completed when a certain amount of time has passed, relative to the start of the run of the current unit of learning. The time is always counted relative to the time when the run of the unit-of-learning has been started. Authors have to take care that the time limits set on role-parts, acts and plays are logical.” |
| | Explanation | The value of the attribute <code>time limit</code> of a <code>Method</code> must be greater than the value of the <code>time limit</code> of any <code>Play</code> . That is, the <code>Play(s)</code> cannot finish after the <code>Method</code> . |
| | Formal Description | $\forall m, p, cm, cp \mid m \in \text{Method} \wedge p \in \text{Play} \wedge cm \in \text{Complete-Method} \wedge cp \in \text{Complete-Play} \wedge \text{play-ref}(p, m) \wedge \text{complete-unit-of-learning-ref}(cm, m) \wedge \text{complete-play-ref}(cp, p) \text{ time-limit}(cm) \geq \text{time-limit}(cp)$ |
| Design Axiom 2 | IMS LD Specification | Page 90: “The same role can be associated with different activities or environments in different role-parts, and the same activity or environment can be associated with different roles in different role-parts. However, the same role may only be referenced once in the same act.” |
| | Explanation | For the same <code>Act</code> , the <code>Roles</code> involved in the execution of the <code>Act</code> are disjoint. |
| | Formal Description | $\forall a, r, rp \mid a \in \text{Act} \wedge r \in \text{Role} \wedge rp \in \text{Role-Part} \wedge \text{role-part-ref}(rp, a) \wedge \text{role-ref}(r, rp) \rightarrow \exists rp1 \mid rp1 \in \text{Role-Part} \wedge rp1 \neq rp \wedge \text{role-part-ref}(rp1, a) \wedge \text{role-ref}(r, rp1)$ |
| Runtime Axiom 1 | IMS LD Specification | Page 25 (item 0.2.1): “The create-new attribute indicates whether multiple occurrences of this role may be created during runtime. When the attribute has the value “not-allowed” then there is always one and only one instance of the role.” |
| | Explanation | If the value of the attribute <code>create-new</code> is “not-allowed”, it can have an only instance of the <code>Role</code> at which it is applied. |
| | Formal Description | $\forall r \mid r \in \text{Role} \wedge \text{create-new}(r) = \text{“not-allowed”} \rightarrow \exists r1 \mid r1 \in r$ |

LD standard, but the semantics expressed in natural language is not included in the ontology.

To deal with this issue, Amorim, Lama, Sánchez, Riera and Vila (2006) propose an ontology also based on the IMS LD that incorporates all its semantics, adding a number of axioms to the conceptual model: they are extracted from the information model where are expressed as natural language restrictions to the values of the concept attributes (table 1). Therefore this ontology does not modify the IMS LD specification, but it incorporates all the semantics in order to enable software programs to manage directly from the representation in the ontology. With this formal specification this ontology, which is developed in F-Logic (Kiefer, Lausen, Wu, 1996) and OWL, has been used to validate the consistency of unit of learnings defined in authoring tools and as a language for knowledge interchanging between agents in collaborative environment (Riera et al., 2005).

CONCLUSION

Ontologies in Education are usually developed following a metadata standard whose intend is capture the semantics of a given theory or specification. Most of metadata standards have been modelled following the XML-Schema language (Thompson, Beech, Maloney, & Mendelsohn, 2004) which is not expressive enough to describe the semantics (or meaning) associated to the elements defined in the metadata. Thus, the main limitations of the XML-Schema language are (Gil & Ratnakar, 2002) that hierarchical relations between two or more concepts cannot be explicitly defined, and general and formal constraints (or axioms) between concepts, attributes, and relations cannot be specified.

To solve these limitations of the XML-Schema language the modelling of metadata standards needs to be enriched in order to describe explicitly and formally the semantics of its elements. Thus misinterpretations or errors are avoided when the instances of the concepts are created. This is the main purpose of the ontologies

developed in the Education field: to favour the interoperability between software programs by representing all the semantics of the metadata, not only the concepts and relations expressed in XML-based formats.

KEY TERMS

Collaborative Learning Environment: Software system oriented to support collaborative learning experience in which two or more agents engage the goal of constructing knowledge based on group discussion and decision-making processes.

Interoperability: Capability to communicate, execute programs, or transfer data among various functional units in a manner that requires the user to have little or no knowledge of the unique characteristics of those units.

Learning Design: Description of a method enabling learners to attain certain learning objectives by performing certain learning activities in a certain order in the context of a certain learning environment. A learning design is based on the pedagogical principles of the designer and on specific domain and contexts variables (e.g., designs for mathematics teaching can differ from designs for language teaching).

Learning Objects: Any reproducible and addressable digital or non-digital resource used to perform learning activities or support activities. Examples are: web pages, text books, text processors, instruments, etc.

Metadata: Information about data, which can be used to comprehend, use, and manage data.

Ontology: Formal and explicit specification of a shared conceptualization, where *conceptualization* refers to an abstract model of a concept in the world; *formal* means that the ontology should be machine readable; *explicit* means that the type of concepts and the constraints on their use are explicitly defined; and *shared* reflects the notion that an ontology captures consensual knowledge accepted by a group.

Ontology Language: Formal language based on a logic paradigm that can represent concepts and the constraints between them. Reasoning capabilities of the language depend on the paradigm in which the language is based on.

Ontology Alignment Overview

INTRODUCTION

At present, ontologies are considered to be an appropriate solution to the problem of heterogeneity in data, since ontological methods make it possible to reach a common understanding of concepts in a particular domain. However, utilizing a single ontology is neither always possible nor recommendable, given that different tasks or different points of view usually require different conceptualizations. This can lead to the usage of different ontologies, although in some cases the different ontologies collectively might contain information that could be overlapping and possibly even contradictory. This, in turn, represents another type of heterogeneity that can result in inefficient processing or misinterpretation of data, information, and knowledge.

To address this problem while at the same time insure an appropriate level of interoperability between heterogeneous systems, it is necessary to find correspondences or mappings that exist between the elements of the (different) ontologies being used. This process is known as ontology alignment.

This article offers an updated overview of ontology alignment, including a detailed explanation of what alignment consists of, and how it can be achieved. First, ontologies are defined using a fusion of different interpretations. This is followed by a definition of the concept of ontology alignment and, using a simple example, some of the most commonly used alignment techniques are illustrated. Subsequently, a case is made for the importance of automating the process of ontology alignment, summarizing some of the main alignment systems currently in use. Finally, in the context of future directions, a discussion is presented of the advantages

associated with integrating ontology alignment into systems that require exchanging information in an automatic fashion.

BACKGROUND

Towards the end of the 20th and beginning of the 21st centuries, the term “ontology” (or ontologies) gained usage in computer science to refer to a research area in the subfield of artificial intelligence primarily concerned with the semantics of concepts and with expressive (or interpretive) processes in computer-based communications. In this context, there are many definitions of ontology, and these definitions have evolved over the years. Gruber offered one of the first definitions of ontology in 1993, as follows (Gruber, 1993):

“An ontology is an explicit specification of a conceptualization”.

Gruber’s definition became the most frequently referenced one in the literature, and became the base or working definition for those working in this area.

At present, ontologies are viewed as a practical way to conceptualize information that is expressed in electronic format, and are being used in many applications including the Semantic Web, e-Commerce, data warehouses, or information integration and retrieval. The basic idea behind these applications is to use ontologies to reach a common level of understanding or comprehension within a particular domain (e.g., a particular industry, medicine, housing, car repair, finances, etc.).

However, certain systems that encompass a large number of components associated with different domains would generally require the use of different ontologies. In such cases, using ontologies would not reduce heterogeneity but rather would recast the heterogeneity problem into a different (and higher) framework wherein the problem becomes one of ontology alignment, thereby allowing a more efficient exchange of information and knowledge derived from different (heterogeneous) data bases, knowledge bases, and the knowledge contained in the ontologies themselves. In this manner, ontology alignment enhances system interoperability.

ONTOLOGY ALIGNMENT

Euzenat et al. defined the problem of ontology alignment in the following manner (Euzenat et al., 2004):

“Given two ontologies which describe each a set of discrete entities (which can be classes, properties, rules, predicates, etc.), find the relationships (e.g. equivalence or subsumption) holding between these entities.”

The key issue in ontology alignment is finding which entity in one ontology corresponds (in terms of meaning) to another entity in one (or many) ontology (or ontologies). Essentially, one might say that ontol-

ogy alignment can be reduced to defining a similarity measure between entities in different ontologies and selecting a set of correspondences between entities of different ontologies with the highest similarity measures.

There are different methods to calculate the similarity measures between entities, and collectively these methods are known as **ontology alignment techniques**. Many of these techniques are derived from other fields (for instance, discrete mathematics, automatic learning, data base design, pattern recognition, among others). Consequently, some of these techniques attempt to compare text strings that describe the entities in the ontologies (terminology-based ontology alignment), while others calculate the similarity measures between entities taking into account the structure of their corresponding ontologies (structural ontology alignment). A complete classification of alignment techniques has been developed by Martínez (Martínez, 2007).

Using a simple example, the following discussion illustrates some of the basic ontology alignment techniques that are currently used. In this example, two simple ontologies are examined, as shown in Figure 1.

The ontologies shown in Figure 1 describe various entities in the real world: sets of elements that share certain characteristics or *classes* (e.g., *Wing*, *Car*, *Bus*, etc.), *instances* of classes (*individuals*) and their *relations* (e.g. a specific *Ferrari F50* belongs to a

Figure 1. An example illustrating the alignment between two ontologies

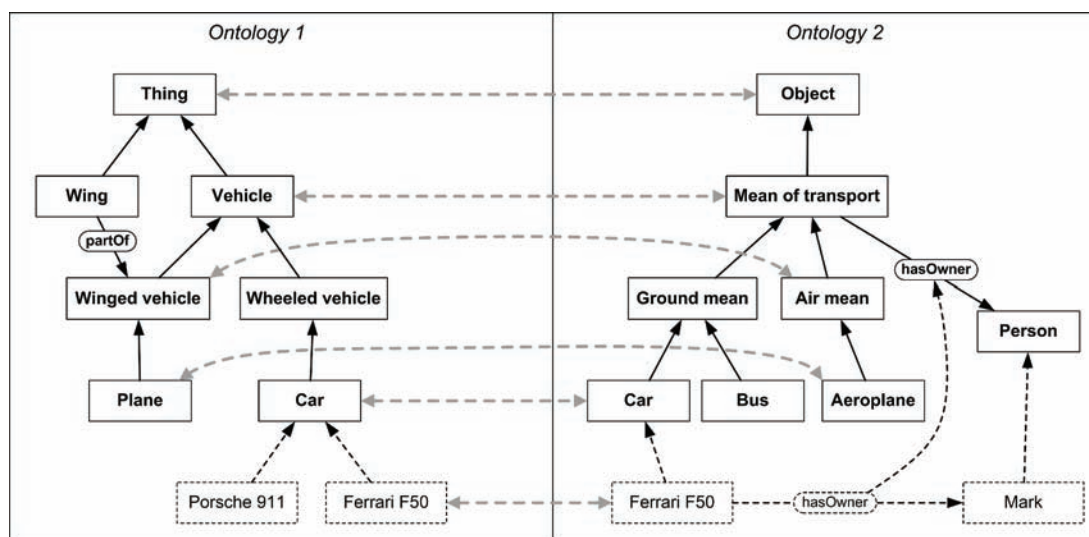

Table 1. Some examples of ontology alignment techniques

| Correspondence | Technique Used | Description |
|---|---|--|
| <i>Thing – Object</i> <i>Vehicle – Mean of transport</i> | Language-based terminological technique | A support tool such as a dictionary is used (e.g. WordNet, 2007) to uncover that both terms are synonymous. |
| <i>Car – Car</i> <i>Ferrari F50 – Ferrari F50</i> | Terminological technique based on text strings | Text string that describe the entities completely coincide, since it can be shown that both entities have the same or similar semantics. |
| <i>Plane – Aeroplane</i> | Terminological technique based on text strings (suffix) | The first term is a suffix of the second, which would indicate that a relationship exists between them. |
| <i>Winged vehicle – Air mean</i> | Structural technique | In the first ontology, <i>Winged vehicle</i> is a child class of <i>Vehicle</i> and parent class of <i>Plane</i> . In the second, <i>Air mean</i> is child class of <i>Mean of transport</i> and parent class of <i>Aeroplane</i> . Since <i>Vehicle</i> was shown to be equivalent to <i>Mean of transport</i> , and <i>Plane</i> refers to the same concept as <i>Aeroplane</i> , both classes would show ascendants and descendants of the same or similar semantics, indicating a semantic relationships between them. |

specific person, *Mark*), as well as three different types of *relationships* between individuals (*isA*, *partOf* and *hasOwner*).

Each one of the ontologies presented in this example has its own set of entities organized according to a specific taxonomy. The two representations arise due to the fact that they correspond to two different perspectives or points of view, each associated with a different domain. However, some pairs of entities can be identified in these ontologies that share the same or similar semantics. Thus, it's probable that the *Plane* class in the first ontology and *Aeroplane* in the second ontology refer to the same concept in general (in the real world), given that the terms that describe them are synonymous terms. Table 1 shows some of the pairs of entities of these ontologies among which semantic similarities could exist, as would be revealed once alignment techniques are applied. The technique that is being applied in each case is shown, along with a description of the technique itself.

Ontology Alignment Systems

Ontology alignment is intended for use in an automated fashion for two primary reasons: first, it's a time-consuming, tedious, and occasionally difficult task, and, second, its true value is revealed when it is integrated into processes that exchange information automatically. This has resulted over the past few years in the

emergence of multiple software tools that have been developed by diverse research groups and well-established international organizations, primarily associated with the academic community. The tools, designed to automatically identify the correspondences that may exist between entities of different ontologies, are called *ontology alignment systems*.

Through the development of these tools, a considerable number of ontology alignment systems have become available. Each one of these systems offers a unique set of advantages, disadvantages, and performance characteristics. Table 2 lists the main ontology alignment systems that are currently available.

An ontology alignment system accepts one (or more) ontologies as input, and provides, as output, a set of correspondences between their elements. This set of correspondences is referred to as *alignment*. The quality of a particular alignment depends on the correctness and completeness of the correspondences it has found. An alignment system is typically based on several of the latest alignment techniques in conjunction with its own methods with the aim of obtaining the most precise and complete alignment possible.

FUTURE TRENDS

At present, there are several ontology alignment systems capable of identifying, with acceptable efficiency, semantic correspondences that may exist

between entities associated with different ontologies. However, the true potential of ontology alignment will be realized when this methodology is integrated in processes that require that information between different systems be exchanged fully automatically. This would be achievable when ontology alignment systems become sufficiently powerful to resolve, in real time and with minimal error, alignment problems in specific domains.

Once these issues are successfully addressed, it will become possible to attain an appropriate level of interoperability between heterogeneous systems that were previously not exploited jointly, thereby representing a high water mark in the field of information and communications technologies. Multiple systems of different characteristics and origins would thus be able to communicate with each other, making it possible to reveal new knowledge that could have previously remained uncovered in disjointed information systems. This would potentially provide human users with a wide range of automated intelligent systems and services capable of interrelating with each other without external assistance, which in turn would considerably facilitate one of the most challenging tasks: the automatic, efficient, and reliable exploitation of large quantities of information.

CONCLUSION

In some applications, the use of a single ontology to fully describe an entire domain is generally not an adequate solution, and it normally becomes necessary to use different ontologies. In such cases, the need arises to find relationships between the elements of the different ontologies, a process known as ontology alignment.

Automation of the ontology alignment process can be reasonably achieved, which is precisely why this process is especially useful in environments or applications that require the automatic interoperability between systems. Currently, there are numerous ontology alignment systems available, and most of these are the result of academic or basic research. These systems can be viewed as software tools capable of finding correspondences or relationships that may exist between the elements of different ontologies. These tools can provide rather remarkable results, especially when taking into account the fact that they essentially remain

works in progress, still in the initial development or testing phases.

In the future, it is expected that ontology alignment systems will reach acceptable levels of robustness, efficiency, and reliability, which would make it possible to apply these systems to processes that automatically exchange data between different systems that individually utilize different ontologies. These automated interactions between systems would not only reduce user intervention but would also automate many time-consuming, complex, and computationally costly tasks that are currently either performed manually or not at all.

KEY TERMS

Class: A set that contain individuals which share certain characteristics. The word *concept* is sometimes used in place of class. Classes are a concrete representation of concepts.

Individual: A object in the domain that we are interested in. Individuals are also known as *instances of classes*.

Interoperability: A state or situation through which heterogeneous systems can exchange data and/or processes.

Mapping: A correspondence found during the process of ontology alignment.

Ontology: A formal and explicit specification of a shared conceptualization.

Ontology Alignment: A process that consists of finding the semantic relationships that may exist between different elements in different ontologies.

Ontology Alignment System: A software tool capable of conducting the alignment of ontologies in an automated fashion.

Ontology Mapping: See ontology alignment.

Ontology Matching: See ontology alignment.

Relation: A link between individuals. In the field of ontologies, relations are also known as *properties*.

INTRODUCTION

Sometimes the use of a single ontology is not sufficient to cover different vocabularies for the same domain, and it becomes necessary to use several ontologies in order to encompass the entire domain knowledge and its various representations. Disciplines where this occurs include medical science and biology, as well as many of its associated subfields such as genetics, epidemiology, etc. This may be due to a domain's complexity, expansiveness, and/or different perspectives of the same domain on the part of different groups of users. In such cases, it is essential to find relationships that may exist between the elements of a specific domain's different ontologies, a process known as **ontology alignment**.

There are several methods for identifying the relationships or correspondences between elements associated with different ontologies, and collectively these methods are called **ontology alignment techniques**. Many of these techniques stem from other fields of study (e.g., matching techniques in discrete mathematics) while others have been specifically designed for this purpose. The key to successfully aligning ontologies is based on the appropriate selection and implementation of a set of those ontology alignment techniques best suited for a particular alignment problem.

Ontology alignment is a complex, tedious, and time-consuming task, especially when working with ontologies of considerable size (containing, for instance, thousands of elements or more) and which have complex relationships between the elements (for example, a particular problem domain in medicine). Furthermore, the true potential of ontology alignment is realized when different information-exchange processes are integrated

automatically, thereby providing the framework for reaching a suitable level of efficient interoperability between heterogeneous systems. The importance of automatically aligning ontologies has therefore been a topic of major interest in recent years, and recently there has been a surge in a variety of software tools dedicated to aligning ontologies in either a fully or partially automated fashion. Some of these tools—generally referred to as **ontology alignment systems**—have been the result of well known and respected research centers, including Stanford University and Hewlett Packard Laboratories, for instance. In Shvaiko & Euzenat, 2007, updated information is given regarding the currently available ontology alignment systems.

Each ontology alignment system combines different alignment approaches along with its own techniques, such that correspondences between the different ontologies can be detected in the most complete, precise, and efficient manner. Since each system is based on its own approximation techniques, different systems yield different results, and therefore the quality of the results can vary among systems. Most of the alignment systems are oriented to solving problems of a general nature, since ontologies associated with a single domain share certain characteristics that set them apart from ontologies associated with other domains. Recently, some systems have emerged that are designed to align ontologies in a specific domain. An example is the SAMBO alignment system (Lambrix, 2006) in the biomedical domain. These and other domain-specific systems can produce excellent results (when used for the domains for which they were designed), but are generally not useful when applied to other domains.

This article presents a classification of the most commonly used, recently developed alignment techniques, supported by simple examples to illustrate the specific techniques underlying different systems. Future directions in ontology alignment are also examined.

BACKGROUND

The key to ontology alignment is to find those entities in one ontology that may correspond to other entities in another ontology. Basically, this can be viewed as finding a similarity measure between elements (or so-called entities) associated with different ontologies, and subsequently selecting the set of correspondences that produce the strongest measures of similarity. There are, however, different ways to compute similarity measures; there are various studies dedicated to the classification of these techniques (Rahm & Bernstein, 2001, Euzenat & Valtchev, 2004, Euzenat et al., 2004, Shvaiko & Euzenat, 2005).

Following these classification schemes (especially those undertaken by Euzenat and Valtchev (Euzenat & Valtchev, 2004) and based on Euzenat et al., 2004), the next section will introduce an abbreviated classification of those ontology alignment techniques that are most commonly utilized by current ontology alignment systems. This condensed classification is centered on the type of element being manipulated by the alignment technique, and complements the taxonomy proposed by Rahm and Bernstein (Rahm & Bernstein, 2001), and—for the purpose of clarity and brevity—summarizes only those alignment techniques that compare on an individual basis a single element in one ontology with another element associated with another ontology (known as local alignment techniques, as in Euzenat et al., 2004).

ONTOLOGY ALIGNMENT TECHNIQUES

Ontology alignment techniques can be classified according to the following (please refer to Figure 1):

1. **Terminological techniques.** These calculate the similarity between text strings and describe several elements in the ontologies (names, labels, and/or comments). There are two types of terminological

techniques: those based on text strings and those based on the language.

1.1. Terminological techniques based on text strings.

These are based on the idea of comparing the structure in text strings, which are viewed as sequences of characters. These techniques consider that the similarity between two terms increases when the similarity between their corresponding text strings also increases, but without considering the underlying semantics in the terms. In this manner, the application of a technique of this type to the terms *Apple* and *Apples* would yield a relatively high measure of similarity, whereas the application of the same technique to the terms *Apple* and *Orange* would yield a lower degree of similarity (or a lower similarity measure), since in the second case the text strings are quite different. The isolated use of these techniques is usually not recommended, since it is preferable to use them in conjunction to other, more powerful alignment techniques; these can be easily illustrated with the following example: it would be erroneous to conclude that the terms *Cream* and *Scream* are highly similar (although their meanings are very different), or that the terms *Student* and *Pupil* are very distinct or dissimilar (although the semantic concepts are generally the same). Some examples of terminological techniques based on text strings are the distance measure proposed by *Hamming* (Hamming, 1950), which counts the number of different characters in two different text strings; the distance measure suggested by *Levenshtein* (Levenshtein, 1966), which examines the minimum number of operations (insertions, deletions and/or substitutions) that are necessary to transform one text string into another; and the distance measure *Jaro* (Jaro, 1989), which analyzes the number and order of two common characters in two text strings.

1.2. Terminological techniques based on language.

These techniques are more complex but more reliable than those previously discussed, and do not treat terms as simple sequences of characters that are independent of one another. Rather, these techniques view terms as groups of elements with meaning (lexima and morphema, i.e., prefixes and suffixes). The main objective of these techniques is to discover the similarity that may exist between terms associated with one concept, although the relationships can be formed by strings of characters that are very different. In other words, these techniques attempt to obviate the different termino-

logical variations that can affect terms that are being mutually compared. These techniques, in turn, can be classified according to whether intrinsic and extrinsic approaches:

1.2.1. Intrinsic techniques. These are oriented toward detecting the similarity between terms that have undergone morphological and syntactical variations (e.g., *Mean of transport*, *Mean of transportation*, *Transportation mean*), as in Porter Stemming Algorithm (Porter, 1980).

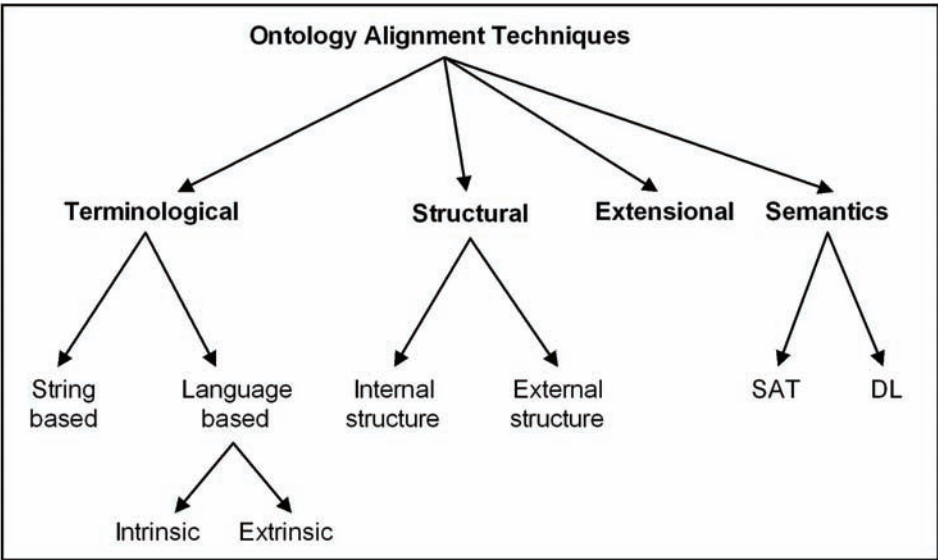

1.2.2. Extrinsic techniques. These consist of utilizing external linguistic resources, such as dictionaries and thesaurus, in order to find the similarity between lexical variations in the same term (e.g., *Mean of transport* and *Vehicle*). External techniques consider the fact that there usually is an equivalence relationship between synonyms, and a subsuming relationship between hyponyms. In this manner, an alignment system based on extrinsic terminological techniques would presumably be capable of detecting, for instance, an equivalence relationship between the terms *Leukocyte* and *White blood cell* (since they are synonymous) and a subsumed relationship between *Myocyte* and *Cell*

(since *Myocyte* is a type of *Cell*). Some of the external linguistic resources most commonly used by such alignment systems currently in use include WordNet (WordNet, 2007), as an English-language resource, or UMLS (National Library of Medicine, 2007) in the medical domain. Other extrinsic techniques that are in use include *multilingual techniques*, dedicated to finding relationships between terms written in different languages (such as the Spanish word *célula* and its English counterpart, *cell*) and using multilingual dictionaries such as EuroWordNet (Vossen, 1997).

2. Structural Techniques. In addition to comparing text strings that describe the entities in each ontology, it is frequently useful to compare the internal structure of the entities themselves, or the relationships that each entity may maintain with other entities (external structure comparison).

2.1. Internal structure comparison techniques. These techniques compare internal characteristics of the entities, such as the rank, cardinality, transitivity, and/or symmetry of its properties (attributes and relationships). For instance, if in one ontology *A* there is an entity *Per-*

Figure 1. Ontology alignment techniques

son with three attributes (*birth_date* of type *date*; *name* of type *string*, and *weight* of type *int*), and in another ontology *B* there is an entity *Human_being* with two attributes (*date_of_birth* of type *date*; and *first_name* of type *string*), a technique of this type might conclude that there is certain similarity between these two entities, since the types of two of the attributes coincide. In this concrete case the technique's conclusion would have been correct: *Person* and *Human_Being* refer to the same concept in the real world. However, it is easy to find cases in which the technique would produce erroneous results. For instance, if the entity in ontology *B* were *Car* with three attributes (*registration_date* of type *date*; *color* of type *string*; and *weight* of type *int*), a comparison of internal structure might suggest that the entities *Person* and *Car* were similar, since the ranks of the three attributes coincide although in reality they are entities associated with very different semantics. Consequently, given that it is frequently possible to find multiples entities in an ontology that represent similar internal characteristics, these techniques tend to be used in conjunction with other techniques (such as terminological techniques). It is probably wise to utilize a method to compare the internal structure during the initial alignment stages, in order to filter pairs of entities that could be related, and subsequently apply other techniques before finally deciding on the overall level of similarity.

2.2. External structure comparison techniques. These techniques compute the similarity that may exist between entities by considering the position that the entities in question occupy within their respective ontologies. The underlying principle is that, if two entities are similar, then there is likely to be some similarity with their adjacent (or neighboring) entities. These techniques tend to treat ontologies as graphs in which each node is a vertex in the ontology and each edge is a relationship between vertices; algorithms that are especially designed to work with graphs are used to find the relationships between elements in the ontologies. As a matter of fact, this problem is equivalent to that of solving a graph homomorphism (Garey, 1979). One of the better known techniques for making the external-structure comparison is the one used by the Anchor-PROMPT ontology alignment system (Noy & Musen, 2000), which is based on the idea that if two pairs of entities in the source ontologies are similar and there are connected paths linking them, then the elements in those paths are also similar.

3. **Extensional techniques.** These extensional (or extensible) techniques compare the extension or length of the classes of ontologies: in other words, their instantiations or examples. This is useful when the information about the entities to be compared is limited but there is additional data or information about their examples; alternately, they are useful as a means of supporting other alignment techniques in order to detect erroneous or misleading correspondences. For instance, if an ontology contains a class denoted as *Human_being* with two instances, *John* and *Mary*, and the other ontology contains a class labeled *Person* with the same instances (*John* and *Mary*), then it could be inferred, by comparing all the instances of the ontologies, that the classes are similar.
4. **Semantic techniques.** These types of techniques attempt to align the elements in the ontologies according to their semantic interpretation. The general approach is based on deductive methods that draw from theoretical models that provide a justification for the results that are obtained. Some examples include the Propositional SATisfiability (SAT) and techniques based on Description Logics (DL).

4.1. SAT techniques: the application of SAT techniques to the ontology alignment problem consists of translating the information associated with pairs of terms between which a mathematical or formulaic relationship could exist. The relationship would be of the form $Axioms \rightarrow rel(element_1, element_2)$, where $element_1$ and $element_2$ are the entities in the ontologies that are being examined to determine if there is a semantic relationship between them, and rel is the relationship that exists between the entities. Subsequently, the validity of the relationship (the aforementioned formula) is evaluated. The advantage of using SAT techniques is that it supports an exhaustive analysis of all the possible correspondences as well as the possibility of selecting only the major correspondences.

4.2. Techniques based on DL: the expressivity of propositional language used by SAT techniques is limited, as they are unable to work with certain types of predicates. However, Description Logics provides the necessary expressivity to code alignment problems as propositional validity problems with greater flexibility. For instance, if an ontology contains the classes *City*,

Worker and *Industrial_city*, as a *City* with more than 600,000 *Workers*, and another ontology contains the classes *Big_town*, *Inhabitant* and *Crowded_big_town*, as a *Big_town* with more than 500,000 *Inhabitants* and it is established that all *Workers* are *Inhabitants* and that *City* is equivalent to *Big_town*, then a DL-based technique could deduce that an *Industrial_city* is a *Crowded_big_town*.

FUTURE TRENDS

Current ontology alignment systems take as input two ontologies and, once the alignment process is executed, yield as output a set of correspondences between their elements. Using up-to-date alignment techniques, this process is still very time consuming and computationally expensive especially in those cases where the input ontologies are large. This may not present a challenge in cases where the same ontologies are always used, since in such cases it would only be necessary to perform the alignment once, and subsequently the correspondences that have been revealed could be reutilized.

However, there are applications or contexts where it becomes necessary to instantly identify which entity in ontology *A* corresponds with an entity in ontology *B*, without previously “knowing” the ontologies. In these cases, current ontology alignment techniques are limited, as is the case with the Semantic Web or the integration of information from different sources that were mutually “unknown” to each other. In these types of problems, it is more important to reduce the computational time that is necessary to carry out the alignment, although the quality of the alignment could be somewhat affected. As a result, it is very probable that in the next few years the field of ontology alignment will see a major thrust being placed on exploring techniques capable of finding correspondences in an increasingly shortened amount of time.

It is also expected that new techniques will emerge that will allow the consultation or usage of external linguistic resources in a more efficient and powerful manner than is now possible. The utilization of external resources is essential in alignment problems associated with specific domains, although current approaches are not capable of achieving optimal usage of these types of resources, thereby wasting a significant amount of potentially useful information.

CONCLUSION

Ontology alignment is an important aspect of practically any domain or application area where it is necessary to use an ontology. There are various approaches to finding semantic correspondences that may exist between elements of different ontologies, known as ontology alignment techniques. This paper has presented a condensed classification of those ontology alignment techniques that are most commonly used today.

Clearly, not all alignment techniques are equally applicable to any problem. For instance, it is not useful to apply an extensional technique to ontologies that have no instances. Consequently, a number of factors ought to be considered when selecting among different alignment techniques for application to a particular problem. Among these are the domain to which the ontologies belong, the language in which the ontologies are expressed, the number and type of elements contained in the ontologies, etc. And, although a particular technique may be applicable to a specific alignment problem, there is also the question of errors. As a result, it should be stressed that aligning two ontologies is not simply the application of an alignment technique in an isolated manner: rather, the goal is mainly to find the appropriate combination of alignment techniques to be applied, such that the strengths of one technique can compensate another technique’s weaknesses and limitations, with the overarching objective of uncovering an optimal set of correspondences between the ontologies of interest.

INTRODUCTION

A genetic algorithm is a global search method based on a simile of the natural evolution. Genetic Algorithms have demonstrated good performance for difficult problems where the function to minimize is complicated. In this work we applied this optimization method to improve the acoustical properties of the Sonic Crystal (Martínez-Sala et al., 1995) (Kushwaha et al., 1994), a kind of structures used in acoustics.

In the last few years the propagation of the acoustic waves in heterogeneous materials whose acoustic properties vary periodically in space have attracted considerable interest. The so-called Sonic Crystals are the typical example of this kind of materials in the range of the acoustic frequencies. These systems are defined as periodic structures with strong modulation of the elastic constants between the scatterers and the surrounding material.

Recently, the strategy to enhance Sonic Crystals properties has been based on the use of scatterers with acoustical properties added. The use of local resonators (Liu et al., 2000) or Helmholtz resonators (Hu et al., 2005) as scatterers have produced very good results. Some authors also have built new structures with scatterers made up of porous material improving the attenu-

ation capability of the Sonic Crystals (Umnova et al., 2006). However, the use of Sonic Crystals as outdoor acoustic barriers requires scatterers made up of robust and long-lasting materials. This is the reason why it seems interesting to analyze the possibility of optimizing the attenuation capability of Sonic Crystals made with rigid scatterers like wood, PVC or aluminium. The creation of vacancies in a Sonic Crystals improves the attenuation capability of the Sonic Crystals (Caballero et al., 2001). However, it does not exist any generic rule about the creation of vacancies in a Sonic Crystals. In fact, similar structures can produce very different acoustic fields behind of them.

Because of the complexity of mathematical functions involved in Sonic Crystals calculus, Genetic Algorithm turns up as a tool specially indicated for this kind of problems (Hakanson et al., 2004) (Romero-García et al., 2006). This procedure can work together with the Multiple Scattering theory which is a self-consistent method for calculating the acoustic pressure including all orders of scattering (Chen & Ye, 2001). Given a starting Sonic Crystals, the Genetic Algorithm generates quasi ordered structures offspring by means of the creation of vacancies that are classified in terms of a cost function based on the pressure values at a specific point. The sound scattered pressure by every

structure analyzed by Genetic Algorithm is performed by a two-dimensional (2D) Multiple Scattering theory. In the present work, it is shown an improvement of the Genetic Algorithm based on Parallel implementation and as a consequence, new and better results are obtained to design Quasi Ordered Structures made with rigid cylinders that attenuate sound in a predetermined band of frequencies.

SONIC CRYSTALS

Sonic Crystals are arrays of scatterers placed periodically in space whose physical properties are different to the surrounding material. In the low frequency range, Sonic Crystals behave as an homogeneous medium with an acoustic impedance greater than that of the air. Then Sonic Crystals can work as refractive devices. Moreover, Sonic Crystals present band gaps, i.e., ranges of sound frequencies where the sound propagation inside the crystal is forbidden. The presence of these band gaps is explained by the well-known Bragg's law. The reflections inside the crystal, and consequently the position of the gaps depend on the lattice constant, i.e., on the geometry of the Sonic Crystals. The existence, in periodic media, of an absolute band gap where the propagation of sound is forbidden for every incidence direction, can have a profound impact on several scientific and technological disciplines, for example, in the design of acoustic filters or acoustic barriers.

Some studies have showed that there are three important parameters for the spectral gap creation (Economolu & Sigalas, 1994). One is the density ratio $\gamma = \rho_s/\rho_h$ between the scattering material and the host material densities. The second one is the filling factor, $ff = Vs/V$, that shows the volume occupied by the scattering material respect to the total volume. The last parameter is the topology used to design the Sonic Crystals. It was demonstrated that the density ratio plays an important role in the gap creation: Sonic Crystals built with scatterers of high density embedded in a host material of low density are better to create the spectral gap than another kind of configurations. Moreover the optimum value of the filling factor, ff , to the gap creation has been ranged between 10% and 50%. In this work we use a Sonic Crystals built by aluminium cylinders of 2 cm of radius as scatterers embedded in air (Network topology). Due to the fact that those structures present a high density ratio, and the

maximum filling factor is $ff = 0,36$, we ensure that our structure is well designed to the gap creation. Now we want to find the best filling factor and space distribution of scatterers that present the best acoustical properties. Genetic Algorithm together with the MST is a good procedure to achieve our objective.

COST FUNCTION AND CHROMOSOME DESCRIPTION

The mechanism used by Genetic Algorithm in this work is the creation of vacancies in the starting Sonic Crystals. Fig. 1 shows the starting Sonic Crystals and a Quasi Ordered Structures offspring generated by Genetic Algorithm by means of the creation of vacancies. Using this procedure we can vary the filling factor and, at the same time, evaluate different spaces of configuration. Each Quasi Ordered Structures will be considered as an individual. The chromosome that represents each Quasi Ordered Structures, is a real vector with values in $[0; 1]$ range. Each coordinate represents the existence or not of a cylinder at a specific position of the scatterer (beginning with the cylinder at the left top corner of the Sonic Crystals and following by columns until right bottom corner, see starting Sonic Crystals at figure 1). Values in $[0; 0.5[$ means there is a vacancy, in opposition values in $[0.5; 1]$ means there is a cylinder. In this work we are interested in maximizing the sound attenuation for a predetermined range of frequencies not dependent on the lattice constant, at a point located behind the crystal.

The acoustic attenuation in a point (x, y) and for a incidence frequency ν is:

$$\text{Atenuación (dB)} = 20 \log \left(\frac{1}{|P_{\text{interfered}}(x, y, X_{\text{cil}}, Y_{\text{cil}}, \nu, r_1)|} \right)$$

where the interfered pressure is determined by the MST. This pressure depends on the position and on the radius of the scatterers and the incidence frequency. In the equation (1) we can see that for a point (x, y) , a value of incidence frequency ν and a value of cylinder radius r_1 , it is possible to find a configuration of cylinders that minimize the $P_{\text{interfered}}$, that means, maximize the acoustic attenuation.

If we are interested in maximizing the sound attenuation in a predetermined range of frequencies at

Figure 1. Starting sonic crystals and a possible quasi ordered structures offspring

a point of coordinates (x, y) we have to define a new function that we have to minimize in order to achieve the maximum acoustic attenuation. To do that, we define our cost function based on the MST

$$J = \frac{\sum_{v=1}^{N_v} p_v}{N_v} + \sqrt{\frac{\sum_{v=1}^{N_v} (\bar{p} - p_v)^2}{N_v^2}}$$

where

$$\bar{p} = \frac{\sum_{j=1}^{N_v} |p_j|}{N}$$

represents the mean pressure in the range of frequencies $[v_1; v_N]$ and N represents the number of frequencies considered in this range. In our case, we use $N = 13$. The second term in equation (2) represents the mean deviation. The variable under study is $\mathbf{x}=(X_{cyl}, Y_{cyl})$ a vector that contains the information about the space configuration of the Quasi Ordered Structures.

PARALLEL GENETIC ALGORITHM

A Genetic Algorithm is an optimization technique that looks for the solution of the optimization problem, imitating species evolutionary mechanism (Goldberg, 1989).

In an optimization problem, there is a function to optimize (cost function) and a zone where to look for (search space). Every point of the search space had an associated value of the function. The different points of the search space are the different individuals of population. Similarly to natural genetic, every different individual is characterized by a chromosome and in the optimization problem, this chromosome is made by the point coordinates in the search space.

The cost function value for an individual has to be understood as the adaptation level to the environment for such individual.

Evolutionary mechanism, that is, the rules for changing populations throughout generations is performed by Genetic Operators. A general Genetic Algorithm evolution mechanism could be described as follows:

From an initial population (randomly generated), the next generation is obtained as:

1. *Some individuals are selected for the next generation. This selection is made depending on adaptation level (cost function value). Such individuals with better $J(x)$ value have more possibilities to be selected.*
2. *To explore search space, an exchange of information between individuals is performed by crossover. That produces a gene exchange between chromosomes. The rate of individuals to crossover is fixed by P_c crossover probability.*

3. An additional search space exploration is performed by mutation. Some individuals are subject to a random variation in their genes. The rate of individuals to be mutated is set by mutation probability P_m .

In this general framework, there are several variation in the Genetic Algorithm implementation; different gene codification, different genetic operator implementation, etc. Implementation for the present work has the following characteristics:

1. Real value codification, each gene has a real value, the interpretation of the chromosome has been detailed in previous section.
2. $J(\mathbf{x})$ is not directly used as cost function. A linear 'ranking' operation is performed (Bäck, 1996). Ranking operation prevents the algorithm from exhausting, it avoids clearly dominant individuals prevailing too soon.
3. Selection is made by the operator known as *Stochastic Universal Sampling (SUS)* (Baker, 1987).
4. For crossover it is used *intermediate recombination* operator (Mühlenbein et al., 1993). Chromosomes sons (x'_1 and x'_2) are obtained through following operation on chromosomes fathers (x_1 and x_2):

$$x'_1 = \alpha_1 \cdot x_1 + (1 - \alpha_1) x_2; x'_2 = \alpha_2 \cdot x_2 + (1 - \alpha_2) x_1; \alpha_1, \alpha_2, \in [-d, 1+d]$$

α_1 and α_2 have to be generated for each gene increasing search capabilities but with a higher computational cost. Implemented Genetic Algorithm has been adjusted as follows: $\alpha_1 = \alpha_2$ and generated for each chromosome, $d = 0$ and $P_c = 0,8$.

5. Mutation operation is done with a probability $P_m = 0,1$ and a normal distribution with standard deviation set to 20% of search space range.

The high computational cost of Sonic Crystal optimization problem produces huge execution time, i.e. in a standard execution (population of 360 individuals, 250 generations) time is around 104 hours. Improvements of execution time have been obtained with a parallel implementation of the Genetic Algorithm described. Several alternative for parallelization are possible

(Cantú-Paz, 1995) the selected one is the configuration Master-Slave. For this architecture there is one processor working as Master, executing tasks of the Genetic Algorithm (ranking, selection, crossover and mutation), and the rest evaluate fitness function of a subpopulation (see Fig. 2).

The Master has to send subpopulation to each Slave, who makes fitness evaluation and returns results to the Master. The Master works in a synchronous way, waiting for all fitness value from all Slaves. After receiving all fitness values the Master performs the evolution to produce the next generation (genetic operators are executed) and sends to the Slaves the new population for fitness evaluation. This type of implementation is the most simple and does not change Genetic Algorithm operators and behaviour. The time reduction is significative since the overall time is divided by the number of Slaves. For the problem proposed, with 5 Slaves, the total execution is reduced to 21 hours.

All developments (Genetic Algorithm and Sonic Crystals models) have been made in Matlab®, parallelization has been done using Matlab Distributed Computing Toolbox and Matlab Distributed Computing Engine.

RESULTS

In this point we present some of our main results. In this work we have analyzed width ranges of 600 Hz

Figure 2. Master/slave architecture for parallel genetic algorithm

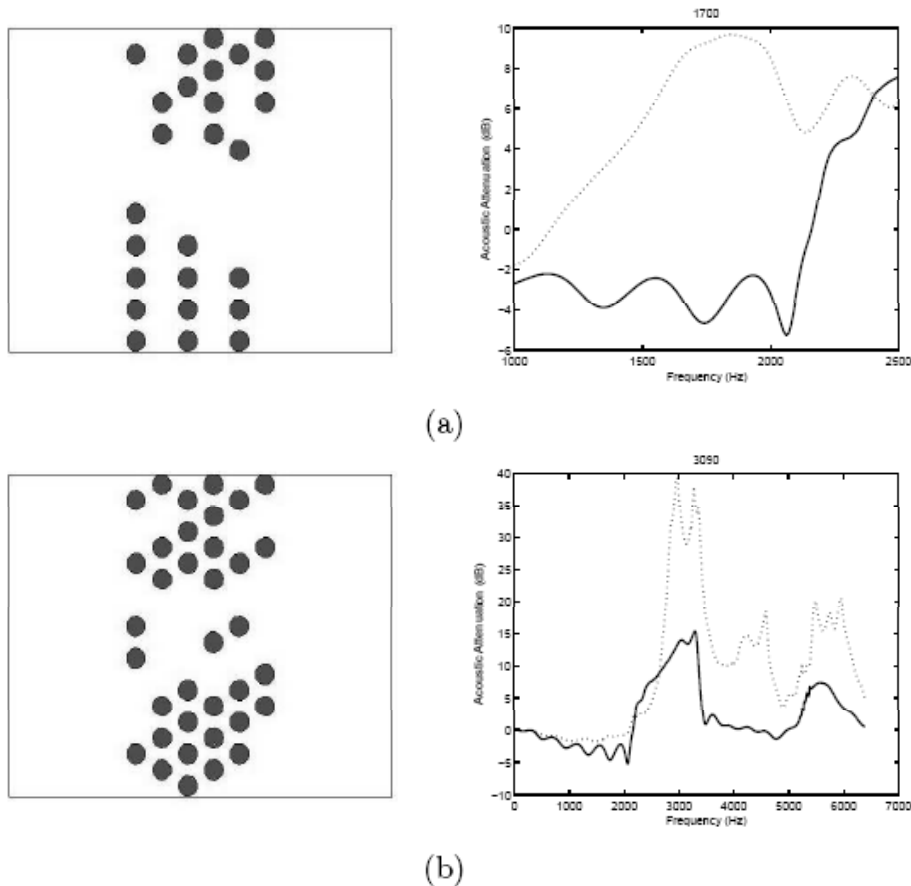

centered at several frequencies (800, 1100, 1300, 1700, 2000, 2300, 3090 Hz) above the first Bragg's peak. On the Fig. 3 we present the results corresponding to the ranges of frequencies centered at 1700 and 3090 Hz respectively. On the left hand of the Fig. 3 we present the schemes of cylinders of the Quasi Ordered Structures generated by the design tool described above. On the right hand the acoustic attenuation spectra calculated by the MST for the starting Sonic Crystals (continuous line) and for the optimized Quasi Ordered Structures (dashed line) is shown.

The creation of attenuation peaks in ranges of frequencies independents on the geometry of the starting Sonic Crystals using rigid scatterers has been the goal

of this paper. As one can see on the Fig. 3, the peak attenuation in the spectra of the optimized Quasi Ordered Structures appears in the chosen frequency range, and this peak is absent in the spectra of the starting Sonic Crystals. Notice that the acoustic attenuation level in the frequency range in the starting Sonic Crystals is much lower than the Quasi Ordered Structures one. Even in some case the starting Sonic Crystals produces sound reinforcement. Moreover, the total number of cylinders in the optimized Quasi Ordered Structures is also lower than the starting Sonic Crystals one. In our results the number of cylinders is ranged between 36.7 % and 60%.

Figure 3. Optimized Quasi Ordered Structures and its spectrum. On the left hand the plot presents the schemes of cylinders of the optimized Quasi Ordered Structures. On the right hand the plots show the acoustic attenuation spectra calculated by the MST for the starting Sonic Crystals (continuous line) and for the optimized Quasi Ordered Structures (dashed line). (a) Optimization corresponding to the central frequency of 1700 Hz. (b) Optimization corresponding to the central frequency of 3000 Hz.

These results constitute a useful tool to design acoustic barriers based on Sonic Crystal with no need for sophisticated scatterers. The technological advantages of using Quasi Ordered Structures with rigid cylinders as scatterers are: high resistance for use outdoors, constructive simplicity and low cost due to the reduction in volume of the crystal.

CONCLUSION

This work shows an important and successful application of a Genetic Algorithm with a parallel implementation. Sonic Crystals open the way for innovative application in noise reduction in several interesting areas as acoustic noise barriers for traffic or general devices for controlling the noise. The Genetic Algorithm demonstrates an adequate optimization for a so complex problem and with the parallel implementation execution times are drastically reduced. Moreover, this method offers the possibility to test a wide range of Sonic Crystals adjustment in a reasonable time.

KEY TERMS

Acoustic Attenuation Spectrum: Representation of the attenuation contribution of each acoustic frequency to a sound.

Cost Function: Mathematical function to minimize in an optimization problem.

Evolutionary Mechanism: Mechanism guided by biological evolution which represents the rules for changing populations throughout generations.

Filling Factor: Volume fraction occupied by the scattering material. Defined as, $ff = V_s/V$, where V is the total volume of the composite, and V_s the volume of the scattering material.

Genetic Algorithm: Global search method based on a simile of the natural evolution.

Quasi Ordered Structure: Given a starting Sonic Crystal (see Sonic Crystal), a quasi ordered structure (Quasi Ordered Structures) is the configuration of scatterers resulting of the creation of vacancies in the Sonic Crystal.

Search Space: Set of all possible situations of the problem that we want to solve could ever be in.

Sonic Crystal: Arrays of scatterers placed periodically in space whose physical properties are different to the surrounding material.

Particle Swarm Optimization and Image Analysis

Stefano Cagnoni

Università degli Studi di Parma, Italy

Monica Mordonini

Università degli Studi di Parma, Italy

INTRODUCTION

Particle Swarm Optimization (PSO) is a simple but powerful optimization algorithm, introduced by Kennedy and Eberhart (Kennedy 1995). Its search for function optima is inspired by the behavior of flocks of birds looking for food.

Similarly to birds, a set (swarm) of agents (particles) fly over the search space, which is coincident with the function domain, looking for the points where the function value is maximum (or minimum). In doing so, each particle's motion obeys two very simple difference equations which describe the particle's position and velocity update.

A particle's motion has a strong random component (exploration) and is mostly independent from the others'; in fact, the only piece of information which is shared among all members of the swarm, or of a large neighborhood of each particle, is the point where the best value for the function has been found so far. Therefore, the search behavior of the swarm can be defined as emergent, since no particle is specifically programmed to achieve the final collective behavior or to play a specific role within the swarm, but just to perform a much simpler local task.

This chapter introduces the basics of the algorithm and describes the main features which make it particularly efficient in solving a large number of problems, with particular regard to image analysis and to the modifications that must be applied to the basic algorithm, in order to exploit its most attractive features in a domain which is different from function optimization.

BACKGROUND

One of the most attractive features of PSO, apart from its effectiveness and robustness with respect to local

minima, is certainly its simplicity, which makes it trivial to implement in any programming language. It is also very versatile and applicable to a large number of optimization problems, virtually to any problem defined within a space for which a metric can be defined. However, its behavior, which mainly depends on the values of three constants, is still far from being fully understood. Extensive work (Engelbrecht2005, Clerc2006, Poli2007a) has provided very important insights into the properties of the algorithm, in studies where the dynamic properties of the swarm have been studied, even if under some restrictive assumptions.

The model which underlies PSO describes the motion of a swarm of particles within the domain of a function, usually termed *fitness function* as for evolutionary algorithms (Eiben 2004, de Jong 2006), seeking for its optimum. Such a motion is comparable to the random motion of a set of independent non-interacting particles within a force field generated by two attractors, one of which is specific to each cell.

The basic PSO equations for a generic particle P within the swarm are

$$\underline{X}_p(t) = \underline{X}_p(t-1) + \underline{v}_p(t) \quad (1)$$

$$\underline{v}_p(t) = \omega * \underline{v}_p(t-1) + C_1 * \text{rand}() * [\underline{X}_{pbest} - \underline{X}(t-1)] + C_2 * \text{rand}() * [\underline{X}_{gbest} - \underline{X}(t-1)] \quad (2)$$

where \underline{v}_p is the velocity of particle P , C_1 and C_2 are two positive constants, ω is the so-called inertia weight, \underline{X}_p is the position of particle P , \underline{X}_{pbest} is the best-fitness point reached by P up to time $t-1$, \underline{X}_{gbest} is the best-fitness point found by the whole swarm, $\text{rand}()$ is a random value taken from a uniform distribution in the interval $[0,1]$.

In its motion, the swarm explores the space effectively, usually converging rapidly to the optimum,

even if its behavior is strongly dependent on the values of ω , C_1 , and C_2 , which must be therefore set very accurately.

PARTICLE SWARM OPTIMIZATION AND IMAGE ANALYSIS

Even if much is still to be learned and discovered about PSO from a theoretical point of view (Kennedy 2007), as regards applications PSO is gaining more and more popularity. As reported in (Poli2007b), a very recent in-depth review of the field, searching the IEEExplore (<http://ieeexplore.ieee.org>) technical publication database by the keyword PSO returns a list of much more than 1,000 titles, about one third of which deal with theoretical aspects. This means that, to date, an incomplete list of PSO application papers adds up to little less than 1,000. Amazingly, about two thirds of them have been published in the last two years.

Image analysis is one of the fields to which PSO is being applied most frequently. As shown by a large number of papers in the image processing and computer vision literature, image analysis problems can be often reformulated as optimization problems, in which an objective function, directly derived from the physical features of the problem, is either maximized or minimized. In most cases, an optimum set of parameters which define the solution are sought using an optimization method. For most real-world problems, usually severely affected by noise or by the natural variability of the instances of the objects which must be detected, this is often inevitable, since methods in which closed-form solutions are directly applied are not usually robust enough with respect to such features. A large number of examples of applications of both traditional and evolutionary optimization methods including, as such, PSO, are reported in the literature.

In this section we will not consider direct applications of PSO as optimizers for an objective function. We will focus our attention on applications in which PSO is not only a way to ‘tune’ a more general algorithm by adapting it to the specific features of the problem at hand, but is directly part of the solution.

We will first introduce some general considerations on image analysis problems, which define the requirements imposed by them. This will allow us to reformulate some typical classes of problems encountered in image analysis, such as object detection and tracking or

image segmentation, to include PSO, or some adapted version of its basic formulation, into the solution. We will then briefly show two examples of applications of PSO to segmentation and object detection, in which the above mentioned considerations have been taken into account.

PSO for Object Detection and Segmentation

In considering the application of PSO to image analysis tasks, one could assume the swarm to fly over the image to detect points or regions of interest. Therefore, the domain of the fitness function becomes the image itself. The fitness value to be assigned to each point can then be defined as a local function of image intensity in a neighborhood of that point, returning high values in points where features similar to the ones which are sought are found.

However, more global information must usually be extracted in image analysis tasks. In fact, while the basic PSO algorithm aims at finding a single optimum within the fitness landscape under exploration, in several image analysis applications more than one optimum (multiple objects) are to be found. This situation is typical of object recognition tasks, where the goal is to identify all possible occurrences of an object of interest characterized by a set of specific features. Similarly, in region-based segmentation, several regions with homogeneous features must be accurately located. Such requirements, encountered also in many other application areas, have led to the definition of several variants of PSO, in which particles are subdivided into a predefined number of sub-swarms, based on some clustering technique (Kennedy 2000, Veenhuis 2006, Passaro 2008), or through speciation (Chow 2004, Bird 2006, Leong 2006, Yen 2006), to achieve a dynamical reconfiguration of the swarm and the detection of an arbitrary number of regions of interest within the search space.

The velocity update function must also be modified in order to let the swarm spread as uniformly as possible over a whole area of interest featuring high fitness values. Such modifications may include introducing repulsive forces between particles, to prevent the whole swarm from converging onto the same point, and limiting particles’ mobility inside a region of interest, to keep the swarm compact and in a stable configuration.

We will first show how these ideas can be applied to two common image analysis problems: region segmentation and object detection. Then we will show results obtained in two real-world problems: the first one was proposed as topic for a competition at GECCO 2006, and consists of detecting and segmenting as precisely as possible large pieces of pasta imaged over a set of noisy backgrounds over which also tiny pasta pieces are scattered, which must be ignored (see Figure 1). The second problem is a sub-task of plate recognition, in which the region occupied by a license plate is to be located within an image (see Figure 2). Even if the two tasks are semantically different, they share some common lower-level features, which allow the same modifications to basic PSO to be used in both cases, with a two-step approach. In the basic step, the image is explored, to focus on regions where interesting features are detected, before a refinement occurs in the subsequent step.

Modified PSO Equations for Image Analysis

In basic PSO, the fitness function is evaluated point by point. In analyzing images using PSO, the search space being the image, using such a local fitness function would make the search extremely sensitive to noise and possibly misleading. If fitness evaluation were just pixel-based, a meaningless isolated pixel yielding high fitness as a result of noise could attract and trap the whole swarm into its neighborhood.

To allow PSO to produce a uniform distribution of particles over each region of interest, the basic PSO algorithm can be modified in two directions:

- Forcing division of the swarm into sub-swarms, able to converge towards different regions of interest,
- Favoring dispersion of the particles all over the regions of interest.

Using the so-called *K-means PSO* (Passaro 2008), in which clusters of particles form based on their proximity within the search space, the former goal can be achieved. To achieve the latter, both the fitness function and the velocity-update equation must be modified.

As concerns the fitness function, a *local fitness* term, which evaluates how “interesting” the neighborhood of one pixel is, can be added to a *punctual fitness* function

term, whose value is computed based only on information carried by the pixel under consideration:

$$fitness(x,y) = punctual_fitness(x,y) + local_fitness(x,y)$$

The *local fitness* term depends on the number of particles, with high punctual fitness, which are neighbors of the pixel located in (x,y) , and is given by:

$$local_fitness = K_0 * number_of_neighbors$$

where *number_of_neighbors* is the number of particles within a pre-defined neighborhood of (x,y) and K_0 is a constant.

This way, the particles are attracted towards the areas where more pixels meet the punctual requirement, keeping away from isolated noisy pixels. This modification enhances the density of particles in the most interesting regions. To cover the whole extension of these regions, also the basic PSO velocity-update equation needs to be modified from (1) to:

$$\underline{v}_p^*(t) = \underline{v}_p(t) + \underline{repulsion}_p$$

The repulsion term can be expressed as

$$|repulsion(i,j)| = REPULSION_RANGE - |\underline{X}_i - \underline{X}_j|$$

where i and j are the particle indices and *REPULSION_RANGE* is the maximum distance within which the particles interact. Values of *repulsion(i,j)* are set to 0 for distances between i and j larger than *REPULSION_RANGE*. The global repulsion term *repulsion_p* for particle P is the average of all repulsion terms acting on it

$$repulsionP = (\sum_{j=1,N} repulsion(P,j)) / n$$

N being the number of particles in the swarm and n the number of particles within the neighborhood of P defined by *REPULSION_RANGE*.

Finally, to produce more stable sub-swarms, a particle with high punctual and local fitness is allowed to stand still with a probability which is linearly dependent on the particle density in its neighborhood, estimated as

$$P\{v_p(t) = 0\} = n/N$$

REAL-WORLD EXAMPLES

Pasta Segmentation

In a color-based region segmentation problem, the fitness function measures the similarity of the pixel color to the expected color of the objects of interest. For pasta, it can be expressed as:

if $(|r(x,y)-g(x,y)| < 30 \text{ and } r(x,y)-b(x,y) > 60)$
 then $punctual_fitness = 30 - |r(x,y) - g(x,y)|$
 else $punctual_fitness = 0$

where $r(x,y)$, $g(x,y)$ and $b(x,y)$ are the red, green, and blue values, respectively, of the pixel located in (x,y) .

Since the goal is to obtain an accurate segmentation, up to pixel precision, and given the large number of pixels belonging to the objects of interest, PSO cannot obviously produce the final solution directly. Instead, it can be used in a pre-processing stage preceding a final thresholding stage which produces the actual output.

Following the PSO rules modified as previously described, the particles will tend to move towards larger pasta regions and stay around there. If one performs a number of PSO runs, assigning to each pixel a score which is directly proportional to the number of times a particle walks through it, the probability of belonging to a large pasta piece can be estimated for each pixel. To better estimate such a probability, avoiding bias deriving from the initial particle locations, each run should start with a different random initialization of the whole swarm. Image regions which eventually have high density of high-score pixels correspond to pieces of pasta. The final result of this stage, that we termed *global search*, is a preliminary segmentation by which the areas where large pieces of pasta are most likely to be found are grossly detected. To refine the segmentation, an algorithm which is very similar to the one used in the previous stage is applied; this time the domain where the swarm can move is limited to smaller regions surrounding pixel clusters whose score was above a threshold in the last phase of the global search. The final segmentation is eventually obtained

Figure 1. Pasta segmentation. Top: Original image (left) and results of global search (right). Bottom: Results of local search (left) and final segmentation (right).

by thresholding the locally updated scores to obtain a binary image. Figure 1 shows the results obtained on one of the images from the image set used in the competition.

Plate Detection

In the license plate detection problem, the low-level feature on which detection is based is the density of high-level values of the horizontal gradient, due to the presence, in the plate, of symbols or symbol elements, which can be encountered when the image is scanned row-wise. Since a color image is available, we can use both color and gradient information, by first considering only those pixels which satisfy the typical features of plates (black characters on a white background for the most recent European standards), and then considering gradient information.

The punctual fitness of a pixel is defined as:

```

if ( |r(x,y) - g(x,y)| > 30 or |r(x,y) - b(x,y)| > 30 or
    |g(x,y) - b(x,y)| > 30 )
    punctual_fitness = 0;
else
    {right_gradient = |intensity(x,y) -
intensity(x+1,y)|;
    left_gradient = |intensity(x,y) -
intensity(x-1,y)|;
    if (right_gradient > left_gradient)
        punctual_fitness = right_gradient;
    else punctual_fitness = left_gradient; }

```

The basic PSO step is virtually the same as in pasta segmentation. However, a different algorithm is used, divided, as well, into a global and a local exploration stage in which, after the most promising areas are firstly

located, the exploration is then refined to determine whether they actually include a plate.

In the global search, the swarm flies over the image until at least one sub-swarm of size greater than a prefixed threshold (50% of the whole swarm) has formed or a given number of iterations has been reached.

Then a local search is performed within regions where sub-swarms of sufficient dimension have formed, starting from the region occupied by the largest swarm; during this second stage: (i) the search is restricted to smaller image regions of interest enclosing the sub-swarms, (ii) the search is re-initialized activating a new full-size swarm in the region of interest, and (iii) the search is run for a pre-set number of iterations. At the end of this stage, a new bounding box, containing all particles, is computed. If this box has an aspect ratio compatible with a license plate, the plate is considered to have been found. Otherwise, the swarm is expanded along its two dimensions, by forcing low-fitness particles to move only horizontally or vertically, in order to reach higher-fitness points and, possibly, to let the bounding box reach the expected aspect ratio; in case of failure, the current region is discarded and the next area detected during the global search is explored.

Figure 2 shows the original image, along with the results of the global and local search, and the final result of the PSO-based algorithm.

The algorithm is computationally very efficient. A number of function evaluations is required to detect the plate, which is lower than just computing the whole gradient image, which would be just the very first step in any 'traditional' computer vision approach. Iteratively re-initializing, in each frame, the swarm location in a neighborhood of the region where the plate has been detected in the previous one, real-time performances can be achieved in tracking the plate in videos acquired at 30 frames per second using a standard PC.

Figure 2. License-plate detection; Original image (left) and results of the detection (right)

The same cannot be said for the pasta segmentation algorithm if high segmentation accuracy is required (about 30 seconds were needed to produce the segmentation in Figure 1 on a 2.8 GHz PC). However, even in that case, if the pieces are just to be grossly located, just a few runs of the algorithm are enough to achieve the goal.

FUTURE TRENDS

Research on PSO and PSO applications to the most various fields is booming nowadays. Image analysis is no exception: according to the INSPEC bibliography database, the number of papers which describe applications of PSO to such a field has increased by almost 50% in the last six months. Results are already very encouraging and suggest that much more is to be expected in the near future.

CONCLUSION

PSO is a versatile and effective optimization technique whose features can be easily adapted to a vast variety of problems, in solving which it can act not only as a “plain” optimizer, but as a more general, flexible search paradigm. The applications described in this chapter have confirmed this, introducing a general framework which can be applied, with few changes, to many other object detection and recognition problems, as well as to other lower-level tasks in computer vision, such as image segmentation.

KEY TERMS

Evolutionary Computation: Collection of techniques, basically aimed at function optimization but applicable to a huge variety of problems, by which the optimum of a function (fitness function) is sought through iterative refinements, according to rules inspired by the laws of natural evolution.

Fitness Function: In evolutionary computation, the objective function which is to be optimized.

Image Analysis: Collection of techniques by which high-level information content is extracted from a digital image using image processing and computer vision techniques.

Particle Swarm Optimization: Optimization technique inspired by the exploratory behavior of animal swarms/flocks/herds in search of food.

Segmentation: In computer vision, a process by which an image is subdivided into regions having homogeneous visual features.

Sub-Swarm: In particle swarm optimization, subset of a swarm, within which the distance between any particle and the closest one is below a pre-set threshold.

Swarm Intelligence: Collection of techniques, usually inspired by nature, in which high-level intelligent behaviors emerge as a result of the interaction among a high number of agents which, individually, perform apparently trivial, low-level tasks.

Personalized Decision Support Systems

Neal Shambaugh

West Virginia University, USA

INTRODUCTION

Decision support systems (DSS) are computerized systems that assist humans to make decisions. Early versions were designed for executives, but over time DSSs were designed for workers at any level in the organization (Keen & Morton, 1978; Rockart, 1979). Due to increasing costs in providing benefits and services, organizations are forcing workers and consumers to take increasing responsibility for insurance, health care, and financial planning decisions. Extreme events, such as terrorism, pandemics, and natural disasters will swamp the capacity of governmental agencies to serve their citizenry. Individuals in affected communities must turn to local agencies or ad hoc groups for assistance. **Personal decision support systems** (PDSS), consisting of databases, model-based expertise, and intelligent interfaces, along with wireless communications, Internet resources, and personal computing, provide sufficient resources to assist informed individuals and groups in solving problems.

This article reviews the typical components of a DSS and the different types of systems that have evolved. The article poses three types of problems facing individuals, including routine problem solving, immediate survival needs, and long-term evolutionary growth. Personal decision support issues of acquiring information, processing information, and dissemination are outlined. Future trends and research opportunities are discussed.

BACKGROUND

DSS aid human thinking by accessing information, integrating this information in some way, structuring decisions, and optimizing decisions (Sprague & Carlson, 1982). These benefits are obtained using three major system features of a DSS, which include a database, which records knowledge; a model base, which models or represents expertise and problem-solving; and an interface, which provides a user with

a means to interact with the other system components (Sprague, 1980).

Powers (2007) characterized DSS in terms of how the system provides assistance. Model-driven DSSs for individuals include spreadsheets. Data-driven DSSs, such as **Executive Information Systems** (EIS), are used by organizations and institutions for strategic and tactical decisions. Communication-driven DSSs can be seen in groupware, video conferencing, and bulletin boards. A document-driven DSS, such as provided by search engines, facilitates document retrieval. A knowledge-driven DSS would be used to solve specialized problems and consist of knowledge represented in terms of rules, procedures, hierarchical frames, or networks. Most recently, web-based DSSs are found in browser searching, intranets, and portal use.

Decision support systems are based on the notion that human reasoning is a rational process, although this is not always the case particularly when humans are faced with complexity and stress (Druzdzel & Flynn, 2000). Experts' decisions in real settings have been shown to demonstrate less quality than linear models (Hastie & Dawes, 2001). Judgmental heuristics reduce cognitive load but decrease the quality of decisions. Characteristics of the DSS components vary in a PDSS in order to compensate for the type of problems faced by individuals. In general for a PDSS the data bases are customized, the model bases are organized along preferential outcomes (e.g., more or less, quantitative), decisions (e.g., lists and value ordering), and uncertainty (specific actions resulting in gain considering constraints and price).

PERSONALIZED DECISION SUPPORT

This article summarizes three problem types facing individuals, including routine problem solving, extreme survival needs, and long-term change. The article outlines system architecture requirements in terms of acquiring and processing of information, interacting

with this information, and the dissemination of information and recommendations.

PDSS Problem Types

The consumer of the 21st century faces numerous **routine problems**, such as career choice, self-improvement, volunteerism, financial planning, retirement, insurance, consumer purchases, health care physician, and personal health. PDSS applications can be seen in health care ranging from point-of-care use of personal data assistants (PDA) to helping patients make decisions on health care (Crawford, 1997; Pierce, 1998). Routine problems consist of complex options with short-term benefits and unknown long-term implications. However, individuals tend to discount the need to make decisions and/or the belief that institutions and governmental agencies will impose decisions on them.

A second problem type can be classified as **survival**. Three examples include natural disasters, terrorism, and pandemics. Natural disasters, such as hurricanes, tornadoes, floods, drought, volcanic eruptions, earthquakes, and meteorite impacts, can also include gradual changes brought about by global warming. Radical changes could involve results of nuclear winter, the shift of the moon's orbit, or pole shifting of the earth's magnetic field. PDSS applications involve disaster management and attempts to connect satellite mapping technology with government agencies (Hegde, Srivastava & Manikiam, 2004). Terrorism provides a more recent survival problem brought about by racial cleansing, violence between religious groups, undermining of governments through corruption and assassination, chemical warfare, and destruction of neighbourhoods and infrastructure. PDSS applications for this problem type has emerged for counter-terrorism applications (Alward, 2004). Pandemics have always occurred throughout human history but have taken on serious implications given technological developments in genetics. Survival problems cannot be predicted, fully characterized, and their impact overwhelms the capacity of a DSS. The value of a PDSS is its proactive potential by identifying national, state, and local resources, recommending action, and triggering the development of institutional support and awareness that did not exist before.

A third problem type is evolutionary or long-term change brought about by a realization that existing decision paths may lead to significant consequences.

Awareness of **change problems** signal a need for people to make long-term proactive decisions in light of multiple paths or scenarios (Schellnhuber, Crutzen, Clark, Claussen, & Held, 2004). Proactive decision-making enables humans to become aware of and address serious consequences of prior decisions by individuals, groups, institutions, and governments, as well as the impact of technological innovations. However, change problems tend to be low priority, require significant resources, and they resist consensus due to their apparent intractability. Simulations and virtual environments may be needed to help citizens interact with potential paths (Stanney, 2002).

Personal Decision Support Architecture

Early views defined a personal DSS as one which focused on a discrete task or decision (Rockart & Bullen, 1986). Examples frequently involved group support, such as Morton's (1971) DSS which involved both marketing and production planning. Keen and Hackathorn (1986) identified three main parts of a personal DSS to include the interface between machine and user, relevant operators (i.e., action verbs, such as "help"), and a database. Development of a personal DSS requires attention to dialogue, refinement of the vocabulary-operators, and evolution of the data structure of the database.

PDSS, as described here, would involve both individual and social needs, and thus would be hybrid versions of several DSS types (Powers, 2007). A PDSS would include mathematical and statistical tools (model-driven) to calculate and make inferences on numerical data. They would retrieve forms and information (document-driven) to support decision-making. They would use information and data as input to address specialized needs (knowledge-driven), such as health care, insurance, career options, and travel planning, among others. The PDSS would consist of both localized (personal computer system) resources and distributed (web-driven) sources where information and computing may be conducted at other sites.

The major systems of a PDSS include databases, reasoning models, interface, and communication options. Each of these four systems can be equated to acquiring information, processing this information in ways that make it amenable to specialized decision modules (e.g., insurance, health-care, travel planning), interacting with the information visually, and com-

Figure 1. PDSS system features

municating or sharing decisions or information with others (see Figure 1).

Acquiring Information

Databases provide a repository for information within any DSS. A personalized version of a DSS would combine local databases, which are developed individually for specific needs, with remote integrated databases. These databases would consist of inconsistent structures, while in the long term some standardization of database structure would be required to develop a personalized integrated database. In addition, ad hoc browsing tends to characterize individual information needs with little regard for organizing this information over the long term.

Processing Information

One of the powerful features of a DSS is its model base. Modeling allows knowledge to be applied across problems and facilitates analysis, explanations, and advocacy (Druzdzel & Flynn, 2000). A model base would include one or more models or representations of expertise ranging from highly specialized (e.g., resale home value) to more general (e.g., model of a learner). Model bases might become object-oriented and incorporated into a PDSS like a software plug-in as needed. Generic versions of a PDSS might include a range of common model components for financial, employment, travel, and health needs and provide simulations to help a user see the implications of decisions. Integrating model bases, as with databases, will require some standardization of model structure along some common categories. Personal patterns of

reasoning may also be archived to provide speed and options for new problems.

The most important and the most challenging to archive and characterize would be context information, an example of unstructured data. A top-down version of a system that would increase the structure of the context-data would be to categorize specific routine contexts, such as financial, health, college selection. Extreme survival categories could include natural disaster and other types of emergencies, crime and terrorism, and pandemics. A bottom-up version of a context representation system would be to identify patterns of information using semantic webs (Hädrich & Priebe (2005), and over time a context-map would be built to characterize particular categories of context.

Interacting with Information

Human dialogue with databases and model bases has used a visual interface, which has typically featured a desktop metaphor. To date users have relied on the metaphor presented to them. A customized interface could still use a desktop metaphor to organize individual problem needs. Other options could be available and custom-developed, which might still rely on an inventory of choices or through some metaphor of choice. Specialized interfaces could be used depending on the problem type (routine, survival, change) to facilitate decision-making. Survival needs require that a user not be presented with too many choices, but rather accurate options to meet an immediate need. These just-in-time visual views present just the information and advice as needed (Lieberman, 2002).

Disseminating Information

The dissemination function, involving the communication and sharing of information and decision options with others, represents a critical system component of a PDSS. While routine problems relate to an individual, problems of survival and change require collaboration. Multi-point sharing of information facilitates decision-making. As wireless becomes a standard feature in many technological devices, dissemination and communication increases for more people. Wireless may become an antiquated term as it becomes transparent and common. Information can be posted for everyone or particular audiences and can be edited or linked to other sources. Much of this information and collaboration may become routed through **personal portals** which structure the information for other users (Shambaugh, 2007).

FUTURE TRENDS

Future Design Metaphor

One feature of a DSS includes the retrieval of information so that decisions can be made based on this information and other sources. Decisions are then based on existing data or data from the past. Goals of profit and cost reduction rely on what-if scenarios and simulations based on assumptions. The focus of individuals, however, is rarely on the past but on the present and the near future. Although the future cannot be predicted, trends based on past and current data provide a picture of where we are in our business, career, or personal life. Making decisions on what we want our life to be for ourselves, our families, and our communities, and even “what business are we in?” necessitates a different view that of **future design**, which is not about predicting the future but rather working towards a future based on our intent to continually cycle through rethinking, designing, and improving.

Government and Community

Responsibility for daily life has always been the domain of the individual and the family. However, the historical reality is that daily life has been continuously constrained by institutions and governments, and by the unseen consequences of technological innovation.

Much of daily life requires navigating these constraints and impacts. However, these tensions can be ameliorated with a move towards taking advantage of personal insight and motivation, a belief in taking responsibility for our lives and our communities, and designing our technological tools for where we want to go, all features of a future design stance.

Research Opportunities

One avenue for research is to add more structure to unstructured data, including information from remote sources, locally-developed databases, and context information. How might these different sources of information be integrated and generalized for use by others? How might context be characterized in terms of re-usable objects?

Modeling expertise has been a long-standing challenge in AI. Modeling decisions for routine problems, those that can be characterized by rules or procedures, and use static domain models, have been the most successful. But a bigger question beyond *What do we know?* becomes *How does the model update itself?*

Decision-making in survival situations will require customized model bases developed specifically for categories of extreme survival. In these type of situations problems are unique and tools will need to be developed see how users’ beliefs about uncertainty and preferences on different outcomes can be visualized (Howard & Matheson, 1984). Evolutionary decision-making, decisions that impact long-term change, will require that model bases evolve from new data. Continually re-defining expertise provides opportunities to analyze what people do on a daily basis (Gigerenzer, Todd, & ABC Research Group, 1999) and how daily, routine expertise becomes critical for individuals and groups of individuals.

Furthermore, inquiry could be conducted on how informed citizens create new societies, **epistemic cultures** that are themselves creating new bodies of knowledge (Cetina, 1999). These new societies could be a block of families, an online community of individuals, or physical neighbourhoods, cities, or countries, or geographic regions. The idea of a PDSS does not limit itself to an individual but to personalizing human life as tools to help individuals, neighborhoods, and cities grow (Longworth, 2006). The conundrum for researchers and designers is realizing that in designing systems that are less logical and more approximations

of the messiness of real life they may be helping humans come to understand what it means to be human (Johnson, 2005).

Another research avenue would study how users might determine the user interface, based on personal metaphors or specific needs, rather than reacting to a standardized metaphor. The study of mental models and how humans project meaning from their experience to a new experience might provide a new means to think and act beyond old rules (Fauconnier & Turner, 2002). Not all problems and situations require the same interface, particularly as the severity of the problem may require a design focused on immediacy and limited choice. Continued collaboration between AI researchers who study representation and reasoning, and those in Human-Computer Interaction (HCI), in which interaction is addressed, may lead to intelligent interfaces with flexible planning, incorporation of human constraint issues (e.g., time, patience, attention, motivation, cognitive demands), and relevance of context (Lieberman & Selker, 2000). Such intelligent interfaces may find themselves first in wireless devices, such as PDAs.

CONCLUSION

Specific skills and responsibilities for living in the 21st century have been pushed down to consumers by organizations and governmental agencies. Individuals now require more time to make important decisions related to their personal and professional lives. These personal decisions add to the growing complexity of human living and require time and resources. Technological developments in computing, networking, and communication provide humans with the capacity for making informed decisions. With the prospect of survival threats and long-term change, informed groups of citizens can initiate proactive priorities in their national, state, and local governments to address these potential problems. A PDSS with features that enable communication and collaboration creates a tool to help individuals take responsibility for decision-making rather than relying on government and institutions. Personalized decision support, characterized by access to Internet resources, integrated knowledge bases, and personal computing and wireless communication, can provide humans with information and recommendations to solve problems, address emergencies, and enhance life.

KEY TERMS

Change Problems: A type of problem with long-term consequences.

Decision Support System (DSS): A computerized system which assists humans to make decisions.

Epistemic Cultures: Bodies of knowledge developed by individuals with a common need.

Executive Information System (EIS): A decision support system that directly supports management decisions.

Future Design: A means of looking and working towards the future rather than predicting the future.

Personal Decision Support System (PDSS): A computerized decision support system which acquires information and organizes the information so that models of reasoning can produce recommendations for further information, resources, or action. Another feature of PDSS is its capacity to openly communicate organized information or decisions to others.

Personal Portals: A computerized site which provides a gateway other sites of individual interest.

Routine Problems: A type of problem faced by individuals involving complexity of choices as well as short-term and long-term implications.

Survival Problems: A type of problem characterized by extreme impacts on individuals and communities.

Planning Agent for Geriatric Residences

INTRODUCTION

Agents and Multi-Agent Systems (MAS) have become increasingly relevant for developing distributed and dynamic intelligent environments. The ability of software agents to act somewhat autonomously links them with living animals and humans, so they seem appropriate for discussion under nature-inspired computing (Marrow, 2000). This paper presents AGALZ (Autonomous aGent for monitoring ALZheimer patients), and explains how this deliberative planning agent has been designed and implemented. A case study is then presented, with AGALZ working with complementary agents into a prototype environment-aware multi-agent system (ALZ-MAS: ALZheimer Multi-Agent System) (Bajo, Tapia, De Luis, Rodríguez & Corchado, 2007). The elderly health care problem is studied, and the possibilities of Radio Frequency Identification (RFID) (Sokymat, 2006) as a technology for constructing an intelligent environment and ascertaining patient location to generate plans and maximize safety are examined.

This paper focuses in the development of nature-inspired deliberative agents using a Case-Based Reasoning (CBR) (Aamodt & Plaza, 1994) architecture, as a way to implement sensitive and adaptive systems to improve assistance and health care support for elderly and people with disabilities, in particular with Alzheimer. Agents in this context must be able to respond to events, take the initiative according to their goals, communicate with other agents, interact with users, and make use of past experiences to find the best plans to achieve goals, so we propose the development of an autonomous deliberative agent that

incorporates a Case-Based Planning (CBP) mechanism, derivative from Case-Based Reasoning (CBR) (Bajo, Corchado & Castillo, 2006), specially designed for planning construction. CBP-BDI facilitates learning and adaptation, and therefore a greater degree of autonomy than that found in pure BDI (Believe, Desire, Intention) architecture (Bratman, 1987). BDI agents can be implemented by using different tools, such as Jadex (Pokahr, Braubach & Lamersdorf, 2003), dealing with the concepts of beliefs, goals and plans, as java objects that can be created and handled within the agent at execution time.

BACKGROUND

During the last three decades the number of Europeans over 60 years old has risen by about 50%. Today they represent more than 25% of the population and it is estimated that in 20 years this percentage will rise to one third of the population, meaning 100 millions of citizens (Camarinha-Matos & Afsarmanesh, 2002). This situation is not exclusive to Europe, since studies in other parts of the world show similar tendencies (Camarinha-Matos & Afsarmanesh, 2002). The importance of developing new and more reliable ways to provide care and support to the elderly is underlined by this trend (Camarinha-Matos & Afsarmanesh, 2002), and the creation of secure, unobtrusive and adaptable environments for monitoring and optimizing health care will become vital. Some authors (Nealon & Moreno, 2003) consider that tomorrow's health care institutions will be equipped with intelligent systems capable of

interacting with humans. Multi-agent systems and architectures based on intelligent devices have recently been explored as supervision systems for medical care for the elderly or Alzheimer patients, aimed to support them in all aspects of daily life, predicting potential hazardous situations and delivering physical and cognitive support.

RFID technology is a wireless technology used to identify and receive information on the move. An RFID system contains basically four components: tags, readers, antennas and software (Sokymat, 2006). The configuration used in the system presented in this paper consists of 125KHZ transponders mounted on bracelets worn on the patient's wrist or ankle, several readers installed over protected zones, with up to 2 meters capture range, and a central computer where all the ID numbers sent by the readers is processed.

MAIN FOCUS OF THE CHAPTER

This article presents an autonomous planner agent for health care. The autonomous nature-inspired health care agent, named AGALZ, is presented. Then, a case study is presented, describing the main characteristics of ALZ-MAS architecture and its agents, including AGALZ, finalizing with initial results obtained after the implementation of a prototype into a real scenario.

Autonomous Nature-Inspired Health Care Agent

We have developed AGALZ, an autonomous deliberative Case-Based Planner (CBP-BDI) agent that integrates with other agents into a multi-agent system, named ALZ-MAS, as a proposal to improve the efficiency of health care and supervision of patients in geriatric residences. AGALZ presents a deliberative architecture, based on the BDI (Belief, Desire, Intention) model (Bratman, 1987). In this model, the internal structure and capabilities of the agents are based on human mental aptitudes, using beliefs, desires, and intentions. Our method facilitates the incorporation of CBR systems (Aamodt & Plaza, 1994) as a deliberative mechanism within BDI agents, facilitating learning and adaptation and providing a greater degree of autonomy than pure BDI architecture. A deliberative CBP-BDI agent is specialized in generating plans and incorporates a Case-Based Planning (CBP) mechanism. The

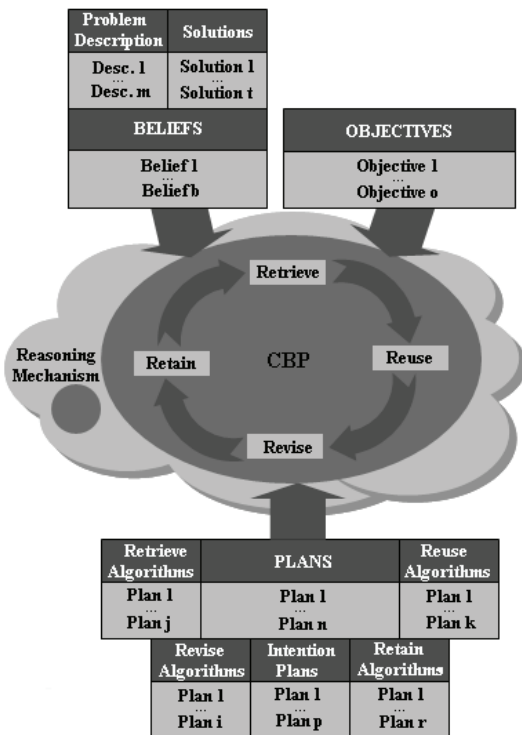

purpose of a CBR agents is to solve new problems by adapting solutions that have been used to solve similar problems in the past (Aamodt & Plaza, 1994), and the CBP agents are a variation of the CBR agents, based on the plans generated from each case. A CBP planner is used for AGALZ to find plans to give daily nursing care in a geriatric residence (Tapia, Bajo, Corchado, Rodríguez & Manzano, 2007). It is very important maintaining a map with the location of the different elements that take part in the system at the moment of planning or replanning, so using RFID technology facilitates enormously the dynamic planning.

CBR is a type of human thinking based on reasoning about past experiences. To introduce a CBR motor into a BDI agent it is necessary to represent the cases used in a CBR system by means of beliefs, desires and intentions, and implement a CBR cycle. A case is a past experience composed of three elements: an initial state or problem description that is represented as a belief; a final state that is represented as a set of goals and a solution (belief); and the sequence of actions that makes it possible to evolve from an initial state to a final state. This sequence of actions is represented as intentions or plans. Figure 1 shows the internal structure of a CPB-BDI agent.

In a planner agent, the reasoning motor generates plans using past experiences and planning strategies, so the concept of Case-Based Planning is obtained (Corchado & Laza, 2003; Glez-Bedia & Corchado, 2002). CBP consists of four sequential stages: retrieve stage to recover the most similar past experiences to the current one; reuse stage to combine the retrieved solutions in order to obtain a new optimal solution; revise stage to evaluate the obtained solution; and retain stage to learn from the new experience.

The CBP cycle is implemented through goals and plans. When the goal corresponding to one of the stages is triggered, different plans (algorithms) can be executed concurrently to achieve the goal. Each plan can trigger new sub-goals and, consequently, cause the execution of new plans. Deliberative CBP-BDI agents, like AGALZ, are able to incorporate other reasoning mechanisms that can coexist with the CBP. AGALZ is an autonomous agent that can survive in dynamic environments. However, is possible to incorporate communication mechanisms that allow it to be easily integrated into a multi-agent system and work coordinately with other agents to solve problems in a distributed way.

Figure 1. CBP-BDI Agent internal structure

The CBP planner constructs plans in such a way that a plan is a sequence of tasks that need to be carried out by a nurse. A task is a java object that contains the date of the requested service, the description of the service and the time limits to carry it out.

For each task one or more goals are established, in such a way that the whole task is eventually achieved. A problem description will be formed by the tasks that the nurse needs to execute, the resources available, and the times assigned for their shift. In the retrieve stage, those problem descriptions found within a range of similarity close to the original problem description are recovered from the beliefs base. In our case, a tolerance of 20% has been permitted. In order to do this, AGALZ allows the application of different similarity algorithms (cosine, clustering etc.). Once the most similar problem descriptions have been selected, the solutions associated with them are recovered. One solution contains all the plans (sequences of tasks) carried out in order to achieve the objectives of AGALZ for a problem description (assuming that replanning is possible) in the past, as well as the efficiency of the solution being supplied. The chosen solutions are combined

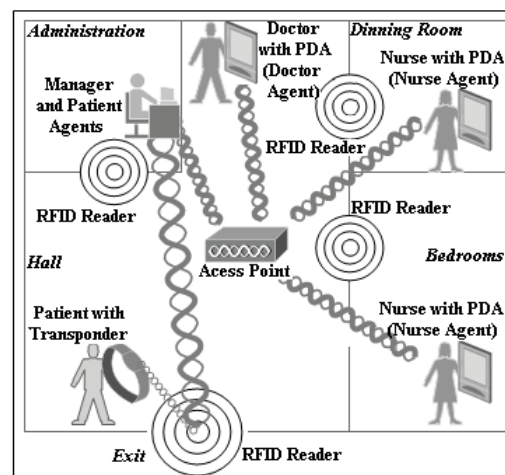

in the reuse stage to construct a plan (Bajo, Corchado & Castillo, 2006; Glez-Bedia & Corchado, 2002). The reuse is focused on the objectives and resources needed by each task, as well as on the objectives that the nurse needs to perform and the resources available in order to carry out the global plan. The objectives that each nurse has are aimed to attend the patients and not exceed eight nurse' working hours. The time available is a problem restriction. The resources necessary for some of the tasks are food, equipment and rooms, among others. AGALZ takes care of incidents and interruptions that may occur during replanning (Bajo, Corchado & Castillo, 2006). Furthermore AGALZ trusts the nurse in the sense that the revision of a plan is made by the nurse. Finally, AGALZ learns about this new experience. If the evaluation of the plan is at least a 90% similar, the case is stored in the cases memory.

Case Study

A prototype of the system has been tested in several geriatric residences, which have been interested in improving the services offered to its patients and has collaborated in the development of the technology presented here, providing their know-how and experimenting with the prototype developed.

Figure 2 shows a basic schema of the wireless technology implemented in the residences. We selected 30 patients to test the system, so the hardware implemented basically consisted of 42 ID door readers, one on each door and elevator, 4 controllers, one at each exit, one

Figure 2. ALZ-MAS wireless technology organization

in the first floor hall and another in the second floor hall, and 36 bracelets, one for each patient and the nurses. The ID door readers get the ID number from the bracelets and send the data to the controllers which send a notification to the Manager agent, located in a central computer. To test the system 30 Patient Agents, 10 AGALZ Agents, 2 Doctor Agents and 1 Manager Agent were instantiated.

ALZ-MAS: Alzheimer Health Care Multi-Agent System

The characteristics of multi-agent systems make them appropriate for implementing into geriatric residences to improve health care of patients (Nealon & Moreno, 2003). A multi-agent system is a distributed system based on the cooperation of autonomous agents. The relationships established between the agents of ALZ-MAS are inspired in human's behaviours (doctors, nurses, patients, etc.) (Marrow, 2000).

Conclusions obtained after studying the requirements of the problem are that ALZ-MAS is composed of four different agent types as shown in Figure 3:

- Patient Agent manages the patient's personal data and behaviour (monitoring, location, daily tasks, and anomalies). Every hour validates the patient location, monitors the patient state and sends a copy of its memory base (patient state, goals and plans) to the Manager Agent in order to maintain backups. The patient state is instantiated at execution time as a set of beliefs and these beliefs are controlled through goals that must be

achieved or maintained. The beliefs that were seen to define a general patient state at the Residences, were: weight, temperature, blood pressure, feeding, oral medication, parenteral medication, posture change, toileting, personal hygiene, and exercise. The beliefs and goals used for every patient depend on the plan (treatment) or plans that the doctors prescribe. Patient Agents monitors the patient state by means of the goals. It is necessary to maintain continuous communication with the rest of ALZ-MAS Agents, especially with AGALZ (through which the nurse can communicate the result of her assigned tasks). At least once per day, depending on the corresponding treatment, Patient Agents must communicate with AGALZ and Doctor Agents. Finally, Patient Agents must ensure that all actions indicated in the treatment are taken out. Patient Agents run on a central computer.

- Manager Agent plays two roles the security role that controls the patients' location and manages locks and alarms; and the Manager role that manages the medical record database and the doctor-patient and nurse-patient assignment. It must provide security for the patients and medical staff and the patients, doctors and nurse assignment must be efficient. This assignation is carried out through a CBR reasoning engine, which is incorporated within the Manager Agent. When a new assignation of tasks needs to be carried out to nurses or doctors, both past experiences, such as the profile of the nurse or doctor, and the

Figure 3. ALZ-MAS architecture: Doctor, AGALZ, Patient, and Manager Agents, within their interactions

needs of the current situation are recalled. In this way, tasks are allocated to nurses. A nurse profile includes nurse's preferences such as holidays, etc.

Manager Agent runs on a central computer.

- Doctor Agent treats patients. It needs to interact with Patient Agents to order treatments and receive periodic reports, with the Manager Agent to consult medical records and assigned patients, and with AGALZ agents to ascertain patients' evolution.
- AGALZ schedules the nurse's working day obtaining dynamic plans depending on the tasks needed for each assigned patient. AGALZ manages nurses' profiles, tasks, available time and resources. The generated plans must guarantee that all the patients assigned to the nurse are given care. Nurses can't exceed 8 working hours. Every agent generates personalized plans depending on the nurse's profile and working habits. AGALZ Agents run on mobile devices, where each nurse can see her plans task by task. A plan can be interrupted for different reasons: a resource fails; a patient suffers a crisis and requires unforeseen attention; a patient has an unexpected visit; etc.

Extracting Results from ALZ-MAS

Figure 4 shows the average number of nurses working simultaneously (each of the 24 hours of the day) before

and after the implantation of the system prototype into a test residence, with data collected for 6 months. The average number of patients was the same before and after the implementation. Tasks executed by nurses were divided in two categories: direct action tasks (where nurses are in contact with patients) and indirect action tasks (where nurses are not directly involved with patients, like monitoring, written reports, managing personal visits to the patients, etc.). During the first 3 months, the problem was analysed, the residence was observed and data was retrieved. Finally averages of the time spent by nurses in the carrying out of the tasks for every patient were obtained, having into account that a task depends on the dependency level of a patient and the nurse skill. For the direct action tasks, the following times were obtained for each patient: 35' cleaning, 18' feeding, 8' oral medication, 30' parenteral medication, 25' posture change, 8' toileting, 60' exercise and 10' others. We are especially interested on time spent on indirect action tasks; daily average times obtained for every kind of task before and after the implementation for each task can be seen on Table 1.

The system facilitates the more flexible assignation of the working shifts at the residence; since the workers have reduced the time spent on routine tasks and can assign this time to extra activities. Their work is automatically monitored, as well as the patients' activities. The stored information may be analysed with knowledge discovery techniques and may help to improve the quality of life for the patients and the efficiency of the centre (Marrow, 2000). The security

Figure 4. Number of nurses working simultaneously in the residence

Table 1. Time (minutes) spent on indirect tasks

| | Monitoring | Reports | Visits | Other | TOTAL |
|--------|------------|---------|--------|-------|-------|
| Before | 167 | 48 | 73 | 82 | 370 |
| After | 105 | 40 | 45 | 60 | 250 |

of the centre has also been improved in two ways: the system monitors the patients and guarantees that each one of them is in the right place, and secondly, only authorised personnel can gain access to the residence protected areas.

FUTURE TRENDS

In the future, health care will require the use of new technologies that allow medical personnel to carry out their tasks more efficiently (Camarinha-Matos & Afsarmanesh, 2002). We are interested in the use of Ambient Intelligence (Ducatel, Bogdanowicz, Scapolo, Leijten & Burgelman), which provides a framework for the development of transparent, ubiquitous and unobtrusive environments. The objective of Ambient Intelligence is to adapt the existing technologies to the human necessities (Emiliani & Stephanidis, 2005). In this sense, the planner proposed in this work must be adapted to any other possible technologies an evaluated in similar environments.

CONCLUSION

We have shown the potential of deliberative AGALZ agents in a distributed multi-agent system focused on health care, providing a way to respond to some challenges of health care, related for example to the identification, control and health care planning. In addition, the use of RFID technology (Sokymat, 2006) on people provides a high level of interaction among users and patients through the system and is fundamental in the construction of an intelligent environment. Furthermore, the use of mobile devices, when used well, can facilitate social interactions and knowledge transfer.

KEY TERMS

Ambient Intelligence (AmI): Refers to electronic environments that are sensitive and responsive to context and people needs and characteristics. It is characterized by systems and technologies that are embedded, context-aware, ubiquitous, non intrusive, personalized, adaptive and anticipatory.

Case-Based Reasoning: A type of reasoning based on the use of past experiences. The purpose of CBR systems is to solve new problems by adapting solutions that have been used to solve similar problems in the past. The main concept when working with CBR is the concept of case, which can be defined as a past experience.

Case-Based Planning: A specialization of Case-Based Reasoning in which the solution proposed by the system is a plan (a sequence of actions).

CBR-BDI: A deliberative BDI agent that incorporates a CBR motor as reasoning mechanism.

CBP-BDI: A deliberative BDI agent specialized in generating plans. It incorporates a Case-Based Planning mechanism.

Multi-Agent System: A system composed of several intelligent autonomous agents, collectively capable of reaching goals solving problems in a distributed way.

Radio Frequency Identification: A wireless technology used to identify and receive information on the move. An RFID system contains basically four components: tags, readers, antennas and software.

Privacy–Preserving Estimation

Mohammad Saad Al-Ahmadi

Oklahoma State University, USA

INTRODUCTION

Data mining has evolved from a need to make sense of the enormous amounts of data generated by organizations. But data mining comes with its own cost, including possible threats to the confidentiality and privacy of individuals. This chapter presents a background on privacy-preserving data mining (PPDM) and the related field of statistical disclosure limitation (SDL). We then focus on privacy-preserving estimation (PPE) and the need for a data-centric approach (DCA) to PPDM. The chapter concludes by presenting some possible future trends.

BACKGROUND

The maturity of information, telecommunications, storage and database technologies, have facilitated the collection, transmission and storage of huge amounts of raw data, unimaginable until a few years ago. For raw data to be utilized, they must be processed and transformed into information and knowledge that have added value, such as helping to accomplish tasks more effectively and efficiently. Data mining techniques and algorithms attempt to aid decision making by analyzing stored data to find useful patterns and to build decision-support models. These extracted patterns and models help to reduce the uncertainty in decision-making environments.

Frequently, data may have sensitive information about previously surveyed human subjects. This raises many questions about the privacy and confidentiality of individuals (Grupe, Kuechler, & Sweeney, 2002). Sometimes these concerns result in people refusing to share personal information, or worse, providing wrong data.

Many laws emphasize the importance of privacy and define the limits of legal uses of collected data. In

the healthcare domain, for example, the U.S. Department of Health and Human Services (DHHS) added new standards and regulations to the Health Insurance Portability and Accountability Act of 1996 (HIPAA) to protect “*the privacy of certain individually identifiable health data*” (HIPAA, 2003). Grupe et al. (2002, Exhibit 1, p. 65) listed a dozen privacy-related legislative acts issued between 1970 and 2000 in the United States.

On the other hand, these acts and concerns limit, either legally and/or ethically, the releasing of datasets for legitimate research or to obtain competitive advantage in the business domain. Statistical offices face a dilemma of legal conflict or what can be called “war of acts.” While they must protect the privacy of individuals in their datasets, they are also legally required to disseminate these datasets. The conflicting objectives of the Privacy Act of 1974 and the Freedom of Information Act is just one example of this dilemma (Fienberg, 1994). This has led to an evolution in the field of statistical disclosure limitation (SDL), also known as statistical disclosure control (SDC).

SDL methods attempt to find a balance between data utility (valid analytical results) and data security (privacy and confidentiality of individuals). In general, these methods try to either (a) limit the access to the values of sensitive attributes (mainly at the individual level), or (b) mask the values of confidential attributes in datasets while maintaining the general statistical characteristics of the datasets (such as mean, standard deviation, and covariance matrix). *Data perturbation* methods for microdata are one class of masking methods (Willenborg & Waal, 2001).

Data Mining vs. Statistical Analysis

Statisticians and researchers conduct surveys and collect datasets that are considered to be large when they contain a few hundred records (Hand, 1998). Traditional statistical techniques are the main (and the most suit-

able) tools for analyzing these datasets to make inferences and estimate population parameters. When the size of datasets is large, traditional statistical analysis techniques may not be the appropriate tools (Hand, 1998, 2000; Hand, Blunt, Kelly, & Adams, 2000). First, traditional statistical analysis may be inappropriate because almost any small difference in a large dataset becomes statistically significant. Second, large datasets may suggest that data was not collected for inference (parameter estimation) about the population. Third, in businesses, a significant amount of data is generated because of unplanned activities (e.g., transactional databases) and not from planned activities (e.g., experiment or survey designs). Therefore, for large datasets, data mining becomes more appropriate.

Examples of large datasets are abundant. Market-Touch, a company located in Georgia, USA, supports direct marketers with data and analytical tools (DMReview.com, 2004). It has a six-terabyte database called Real America Database (RADBO), which provides information about more than 93 million households and 200 million individuals. It is updated monthly with more than 20 million records.

Statistical agencies also experience this phenomenon of rapidly growing datasets. The US Census Bureau (Census, 2001) reported that the Census 2000 data consist of “*information about the 115.9 million housing units and 281.4 million people across the United States.*” These large sizes suggest the need for analytical tools that are suitable for large datasets, and again, data mining tools naturally come into play. Consequently, the Bureau provides programs with data mining capabilities such as DataFerrett (Federated Electronic Research, Review, Extraction and Tabulation Tool), which can be used to analyze and extract data from TheDataWeb - a repository of datasets that cover more than 95 subject areas.

Motivation for Privacy-Preserving Data Mining (PPDM)

Data mining techniques may lead to more significant threats to privacy and confidentiality than statistical analysis. Domingo-Ferrer and Torra (2003) make a connection between SDL methods and some data-mining AI (artificial intelligence) tools and suggest that disclosure and re-identification threats can be magnified.

DM tools can be used to aggregate or combine masked copies of a specific original dataset to reverse masking and re-build the original dataset, which raises a *confidentiality* issue. This is particularly true when unsophisticated SDL techniques are used and many masked copies are released. DM tools can also be used to enforce data integrity and consistency in distributed datasets by re-identifying different records belonging to the same individual raising a *privacy* issue.

These concerns about privacy and confidentiality when DM tools are used have led to the birth of privacy-preserving data mining (PPDM). The main goal of PPDM is to find useful patterns and build accurate models from datasets without accessing the individuals' precise original values in records of datasets (Agrawal & Srikant, 2000).

Related Work in Privacy-Preserving Data Mining (PPDM)

Similar to the classification of data mining (DM) techniques proposed by Berry and Linoff (2004), privacy-preserving data mining (PPDM) techniques can be classified as: (a) directed PPDM techniques: privacy-preserving estimation and privacy-preserving classification, and (b) undirected PPDM techniques: privacy-preserving association rules and privacy-preserving clustering.

Directed PPDM techniques try to model the relationship between a dependent variable and other (independent) variables in masked datasets. *Estimation* deals with continuous dependent variables and *classification* with categorical or binary dependent variables. The models obtained from the masked data using directed PPDM techniques must be the same (or similar) to that from the original dataset at the aggregate level, while protecting the privacy and confidentiality at the individual level.

In undirected PPDM, there is no concept of a dependent variable. Instead, the goal is to find unknown patterns and rules. *Clustering* is used to discover (and usually profile) homogenous subsets of data records and often used as a preprocessing tool (to segment the customer base, for example) before applying other DM technique (Berry & Linoff, 2004). *Association rules* are used to discover which items go together (are associated). Again, the goal of PPDM is to obtain similar

patterns from both the masked and original data. Figure 1, reproduced from Al-Ahmadi (2006), shows an abstract view of privacy-privacy data mining (PPDM) literature broken down by technique. Details on the references may be found in Al-Ahmadi (2006).

PRIVACY-PRESERVING ESTIMATION (PPE)

We focus on privacy-preserving estimation (PPE) (also called privacy-preserving regression). PPE is still in its infancy compared to other PPDM methods, with some approaches showing promise. Sanil et al. (2004) proposed an algorithm for computing the exact coefficients of multiple linear regression for *vertically*-distributed (or partitioned) dataset without sharing original values. The dataset is assumed to contain a single shared, non-confidential dependent variable. The unshared confidential, independent variables are owned by more than two parties (agents) involved in the estimation

process. It utilizes the secure summation algorithm (Benaloh, 1987; Clifton, Kantarciloglu, Vaidya, Lin, & Zhu, 2002) to share a statistical summary (total), populated partially by each party without revealing how much each party contributes to that statistic. This total is needed for estimating the regression coefficients iteratively. Thus, each party can calculate accurately, the coefficients of the variables they own and share them with other parties.

Karr et al. (2004) suggest two approaches for building multiple linear regression on the union of a *horizontally*-distributed dataset. The first approach, (*secure data integration*) integrates horizontally-distributed datasets from multiple parties (agents) into one dataset, while protecting the identity of the data source. Each party could locally run linear regression analysis on the integrated dataset. This approach only protects the identity of the data sources (i.e. the identity of the involved parties, not the identity or confidentiality of surveyed human subjects). A second approach is based on the additive nature of the linear regression analysis.,

Statistics (rather than data) needed to calculate the least squares estimators of linear regression coefficients are shared and integrated in a secure manner using the secure summation algorithm (Benaloh, 1987; Clifton et al., 2002; Schneier, 1996).

Remote regression servers (cf. Duncan & Mukherjee, 2000; Keller-McNulty & Unger, 1998; Schouten & Cigrang, 2003) are access-limitation (not masking) methods for protecting microdata for building linear regression models. Although this approach builds linear regression models using original values, users do not usually have any means of checking the fit of their models. Reiter (2003) proposed a method to overcome this limitation based on releasing artificial, simulated (marginally-wise) dependent and independent variables, residuals and fitted values that mimic the original relationships of the built models.

Because many multivariate methods, including multivariate linear regression, depend on matrix computations such as matrix multiplication and matrix inverse, Du et al. (2004) proposed secure two-party matrix computations protocols. These enable two agents to collaboratively run matrix computations without knowing or accessing the other party's original, sensitive values, and without the involvement of a third party.

The above approaches to PPE, they are focused exclusively on linear relationships. This makes them somewhat limited for more general purpose PPE, where nonlinear relationships found in the original data may need to be preserved in the masked data.

Data-Centric Approach (DCA) for Privacy-Preserving Data Mining

One of the problems with many existing PPDM approaches is that they create a dependency between the algorithm and the dataset (Thuraisingham, 2005); see, for example, Agrawal and Srikant (2000). The PPDM algorithm is usually a modification of a specific DM algorithm, for a specific protection technique. The masked data can therefore be analyzed using only that particular (tailored) data mining algorithm. Otherwise there is no guarantee that the results from analyzing the masked dataset will be the same as, or similar to, that from analyzing the original dataset. This is not a good idea because data miners usually employ more than one algorithm to mine a dataset. Examining all data mining algorithms, as well as modifying them, is not feasible.

Second, once a dataset is released, there is no guarantee as to which algorithm might be applied possibly leading to incorrect conclusions and actions.

Instead, as suggested by Al-Ahmadi et al. (2004), datasets should be protected or masked without reference to a specific DM algorithm. Oliveira and Zaiane (2004b) support the concept of a Data-Centric Approach (DCA) which supports the concept that the masking algorithm must *not* be tied to the data mining algorithm, but must be based on the characteristics of the dataset and its subsequent use. For example, a good PPE algorithm will mask the dataset based on the kind of relationships that need to be maintained in the masked dataset. However, it will not mandate that a particular data mining algorithm should be used to perform the estimation using the masked data. Al-Ahmadi (2006) demonstrates some PPE algorithms that utilize the DCA approach. Oliveira and Zaiane (2004a) also applied the DCA concept by developing a new PPDM clustering algorithm called Rotation-Based Transformation (RBT) that allows any distance-based clustering algorithms to be used on the masked datasets.

FUTURE TRENDS

Data perturbation and SDL masking methods can be a good starting point for implementing DCA in PPE and PPDM. One protection method used is Simple Additive Data Perturbation Method (SADP) (Traub, Yemini, & Wozniakowski, 1984), which has undesirable characteristics in terms of data utility and data security (Muralidhar, Parsa, & Sarathy, 1999). Most of the newer and more sophisticated data perturbation and SDL masking methods, such as C-GADP (Sarathy, Muralidhar, & Parsa, 2002), IPSO (Burridge, 2003), EGADP (Muralidhar & Sarathy, 2005) and data shuffling (Muralidhar & Sarathy, 2003, 2006), have not been investigated in the PPE and the general PPDM domain. The only exception is the GADP method (Muralidhar et al., 1999), which appears in a few privacy-preserving classification studies (Islam & Brankovic, 2004; Wilson & Rosen, 2002, 2003; Wilson, Rosen, & Al-Ahmadi, 2005a, 2005b). Hence, there is a need to investigate the possibilities of using some of these advanced SDL masking methods in PPE and PPDM.

From another perspective, different types of relationships can exist in a dataset. For instance, multivariate

normal datasets guarantee that all existing relationships among variables are linear. For this special case, some existing SDL masking methods are readily available and can perfectly preserve linear relationships. This is due to the fact that most SDL methods are developed to preserve linear relationships. However, most (business) datasets contain nonlinear relationships (Zhang, 2004), which can be monotonic or non-monotonic (Fisher, 1970). “A truth about data mining not widely discussed is that the relationships in data the miner seeks are either very easy to characterize, or very, very hard,” (Pyle, 2003, p. 314). Therefore, there is a need to develop masking methods for PPE and PPDM to maintain more complicated types or relationships (i.e. monotonic nonlinear and non-monotonic relationships).

CONCLUSION

This article introduced privacy-preserving data mining (PPDM) and related concepts. It gave a brief overview of the four main PPDM techniques: estimation, classification, clustering, and association rules. Then, it reviewed some of the work that has been done in Privacy-Preserving Estimation (PPE). It concluded by discussing some of the possible future trends in PPDM and PPE including the need for research into data-centric SDL-based masking techniques for solving complicated PPE problems.

KEY TERMS

Confidentiality: The status accorded to specific attributes (such as salary) in datasets, whose original values should not be revealed. Generally, some type

of protection such as masking must be provided before these confidential attributes are disseminated.

Data Mining Algorithm: A systematic, practical method to implement a data mining *technique*. Different algorithms can be used to implement the same data mining *technique*. For example, decision trees algorithms (CART, C4.5, C5, etc.) and logistic regression are among the algorithms of the *classification* data mining *technique*.

Data Mining Technique: The main purpose or objective of the data mining modelling process. Each technique can be implemented using different DM *algorithms*.

Data-Centric Approach (DCA): The concept that data protection techniques must be independent of (standard) DM algorithms. That is, the masked data must be analyzable using multiple DM algorithms while providing results comparable to the results from analyzing the original data.

Privacy: Privacy is the desire of individuals to control their personal information. Generally, in the SDL literature, it relates to the identity of an individual, while confidentiality relates to specific information about the individual (such as salary).

Statistical Disclosure Limitation (SDL) or Statistical Disclosure Control (SDC): A set of methods that attempt to protect privacy and confidentiality of data, while preserving the overall statistical characteristics of original datasets (such as mean and covariance matrix) in the protected dataset.

Protein Structure Prediction by Fusion, Bayesian Methods

INTRODUCTION

Prediction of protein secondary structure (alpha-helix, beta-sheet, coil) from primary sequence of amino acids is a very challenging and difficult task, and the problem has been approached from several angles. A protein is a sequence of amino acid residues and can thus be considered as a one dimensional chain of ‘beads’ where each bead correspond to one of the 20 different amino acid residues known to occur in proteins. The length of most protein sequence ranges from 50 residues to about 1000 residues but longer proteins are also known, e.g. myosin, the major protein of muscle fibers, consists of 1800 residues (Altschul et al. 1997). Many techniques were used many researchers to predict the protein secondary structure, but the most commonly used technique for protein secondary structure prediction is the neural network (Qian et al. 1988).

This chapter discusses a new method combining profile-based neural networks (Rost et al. 1993b), Simulated Annealing (SA) (Akkaladevi et al. 2005; Simons et al. 1997), Genetic algorithm (GA) (Akkaladevi et al. 2005) and the decision fusion algorithms (Akkaladevi et al. 2005). Researchers used the neural network (Hopfield 1982) combined with GA and SA algorithms, and then applied the two decision fusion methods; committee method and the correlation methods and obtained improved results on the prediction accuracy (Akkaladevi et al. 2005). Sequence profiles of amino acids are fed as input to the profile-based neural network. The two decision fusion methods improved the prediction accuracy, but noticeably one method worked better in some cases and the other method for some other sequence profiles of amino acids as input (Akkaladevi et al. 2005). Instead of compromising on

some of the good solutions that could have generated from either approach, a combination of these two approaches is used for obtaining better prediction accuracy. This criterion is the basis for the Bayesian inference method (Anandalingam et al. 1989; Schmidler et al. 2000; Simons et al. 1997). The results obtained show that the prediction accuracy improves by more than 2% using the combination of the decision fusion approach and the Bayesian inference method.

BACKGROUND

A lot of interesting work has been done on protein secondary structure prediction problem, and over the last 10 to 20 years the methods have gradually improved in accuracy. The most successful application of neural networks (Hopfield 1982) to secondary structure prediction was obtained by Rost and Sander (Rost et al. 1993b; Rost et al. 1993c; Rost 1996; Rost et al. 1994), which resulted in the prediction mail server called PHD (Rost et al. 1993c). Using profile-based neural network and a few other methods, the performance of the network is reported to be up to 67.2% (Rost et al. 1993b).

In the problem of the protein secondary structure prediction, the inputs are the amino acid sequence profiles while the output is the predicted structure (also called conformation, which is the combination of alpha helices, beta sheets and loops) (Banavar et al. 2001; Branden et al. 1999). A typical protein sequence and its conformation class are shown below:

ProteinSequence: ADADADADCCQQFFFAAAQQA-QQA
Conformation Class: HHHH EEEE HHHHHHHH

H stands for Helical, E for Extended, and blanks are the remaining coiled conformations.

A typical protein contains about 32% alpha helices, 21% beta sheets and 47% loops or non-regular structure (Rost et al. 1993b). It is possible to predict loop regions with higher accuracy than alpha helices or beta sheets (Rost et al. 1993c). The *seven-fold cross-validation* technique is used on the set of 126 non-homologous globular proteins from (Rost & Sander, 1994), which is called the RS126 data set (Rost et al. 1994) for training and testing purpose.

The protein secondary structure accuracy is calculated by using the three-state per-residue accuracy (Q_3), which gives the percentage of correctly predicted residues in either of the three states (classes), alpha helix, beta strand or loop region (Qian et al. 1988; Rost 1996):

$$Q_3 = \left[\frac{(P_\alpha + P_\beta + P_{loop})}{T} \right] \times 100\%$$

P_α , P_β and P_{loop} are number of residues predicted correctly in state alpha helix, beta strand and loop respectively while T is the total number of residues.

PROTEIN SECONDARY STRUCTURE PREDICTION BY VARIOUS APPROACHES

In this research the RS126 dataset is used, which contains 126 sequences with approximately more than 23,300 amino acid positions and 20 amino acids (Rost et al. 1994). Orthogonal encoding scheme is used for the input which is sent to the profile-based neural network.

Protein Secondary Structure Prediction using sequence profiles - The profile-based neural network is used for this research. Using profiles at the input level generally has been shown to yield better results than using profiles at the output level (Baldi et al. 1999; Rost et al. 1993b). Using this approach the secondary structure prediction accuracy (Q_3) is 66.8%.

GA and the profile-based Neural Networks for protein secondary structure prediction - The predicted structure from the profile-based neural network is given to GA; the GA does a series of mutation and crossover operations on the predicted structure from

the profile-based neural network to generate new solutions (offspring's) (Akkaladevi et al. 2005). After the offspring is generated; the fitness of this new offspring is calculated by again comparing to the true structure already known by using the Q_3 function. The GA accepts or rejects this solution depending on the fitness value, which in this case is the prediction accuracy Q_3 . Finally at this point the error value is calculated and back-propagated to adjust the weights of the profile-based neural network. The mutation probability for GA in this research is set at 0.25, number of generation's at 75, population size at 30 and the crossover probability as 100% (Akkaladevi et al. 2005). Using this approach the secondary structure prediction accuracy (Q_3) is 69.2%.

SA and the profile-based Neural Networks for protein secondary structure prediction - The predicted structure from the profile-based neural network is sent to the SA algorithm for further processing by the SA algorithm (Akkaladevi et al. 2005). The SA algorithm generates new solutions and compares it with the true secondary structure which is already known to calculate the prediction accuracy Q_3 . The error is then calculated by determining the value of Q_3 . This error value is then back-propagated to adjust the weights of the profile-based neural network. The starting temperature for SA in this research is set at 600, the final temperature at 0.20, the temperature cooling rate at 0.84, and the number of iterations per temperature at 20 (Akkaladevi et al. 2005). Using this approach the secondary structure prediction accuracy (Q_3) is 68.3%.

Prediction of protein secondary structure using the Committee method and the profile-based Neural Network - In the committee based method (Mazurov et al. 1987) of applying decision fusion the secondary structure values are calculated using a combined profile-based neural network (PNN) with GA, a combined profile-based neural network with SA, and the independent profile-based neural network. The output obtained from the profile-based neural network, combined profile-based neural network plus GA and combined profile-based neural network plus SA is routed to the decision fusion algorithm, for fusing the solutions as shown in Figure 1 (Akkaladevi et al. 2005).

The decision fusion (Abidi et al. 1992) algorithm works on the basis of a committee (committee method or voting method), where each individual in the committee decides on the best solution according to pre-determined rules and then cast their vote for the

Figure 1. Fusing the various solutions according to the fusion rules

best approach (Mazurov et al. 1987). In the event of a tie, the tie is broken by one more rule; the priority assigned to each algorithm. The algorithm with the highest priority wins. The Committee fusion algorithm is outlined below:

1. Given a secondary structure output obtained by profile-based neural network of N_i elements, where $i = 1, 2, \dots, n$. (Here for 'H' we assume a value of 2, for 'E' a value of 3, and for 'C' a value of 4. These are arbitrarily chosen values). Similarly represent output from GA and SA by G_i and S_i respectively
2. Calculate the following values:

$$G = \sum_{i=1}^n (N_i - G_i)^2 \quad (1)$$

$$S = \sum_{i=1}^n (N_i - S_i)^2 \quad (2)$$

$$N = 0 \quad (3)$$

3. Compute $N_i - G_i$. If $N_i - G_i > 0$, then $(\text{bin}+) \leftarrow N_i - G_i$ else if $N_i - G_i < 0$, then $(\text{bin}-) \leftarrow N_i - G_i$, where bin+ and bin- are the so called positive and negative bins. If the result of the operation is zero, it is not stored in any of the bins.
4. Evaluate bin+ and bin-, the positive and negative bins for G ; if they are equal or if the positive bin has a higher count compared to the negative bin G is assigned a positive sign (+G), else G is

assigned a negative sign (-G). Always consider $N=0$.

5. Repeat steps 3 and 4 to calculate S .
6. Use $\max(N, G, S)$ to be the secondary structure for calculating Q_3 which is used to determine the error for back-propagation for weight adjustments. Each algorithm votes for the best solution by comparing its value with the other algorithms values. The algorithm with the majority votes wins the race. In the event of a tie, the tie is broken according to the algorithm's priority, and the algorithm which wins calculates the prediction accuracy using the function Q_3 to determine the error that is to be back-propagated to the profile-based neural network for weight adjustments.
7. The profile-based neural network (PNN) secondary structure values are assigned the highest priority, followed by the combination of profile-based neural network and GA (PNN+GA), and then followed by the combination of profile-based neural network and SA (PNN+SA) (Akkaladevi et al. 2005). Using this approach the secondary structure prediction accuracy (Q_3) is 70.8%.

Prediction of protein secondary structure using the Correlation method and the profile-based Neural Network - This method is very similar to the committee method but with some minor changes (Akkaladevi et al. 2005; Ho et al. 1994). In this method the algorithm that wins after decision fusion is applied is used to calculate the prediction accuracy using the function Q_3 to determine the error that is to be back-propagated to the profile-based neural network for weight adjustments.

After this adjustment of weights on the profile-based neural network, the previous protein sequence is again used for testing purpose to check whether better prediction accuracy is achieved or not. Here the new weights are used if we get an improvement of more than 1.5%, otherwise from the previously calculated prediction accuracies of (PNN), (PNN+GA) and (PNN+SA), the method which produces the highest prediction accuracy is chosen to determine the error that is to be back-propagated to the profile-based neural network for weight adjustments (Akkaladevi et al. 2005). Using this approach the secondary structure prediction accuracy (Q_3) is 71.4%.

PREDICTION OF PROTEIN SECONDARY STRUCTURE BY THE BAYESIAN INFERENCE METHOD

In this method the Bayesian inference method is applied on the output generated by the committee and correlation methods of decision fusion (Anandalingam et al. 1989; Schmidler et al. 2000). In the Bayesian inference approach both these methods are used by assigning a specific probability value to them, and then generating a new value using the Bayesian equation (Anandalingam et al. 1989; Simons et al. 1997). This new value obtained is used to decide between the two methods (committee method and correlation method) to be used for calculating the error that is to be back-propagated to the profile-based neural network for weight adjustments. The following Bayesian equation is used to calculate the value for judging between the two methods (Anandalingam et al. 1989).

$$P(H_1 | D) = \frac{P(H_1) \times P(D | H_1)}{P(H_1) \times P(D | H_1) + P(H_2) \times P(D | H_2)}$$

To illustrate, let H_1 corresponds to correlation method, and H_2 corresponds to committee method. Since the correlation method produces better prediction accuracy compared to the committee method, for our first instance we assume that $P(H_1) = 0.51$, and $P(H_2) = 0.49$ (assigning more probability for choosing correlation method as this method produces better prediction accuracy compared to the committee method).

For example if we obtain a prediction accuracy of 71% using the correlation method and a prediction

accuracy of 70.5% using the committee method, then $P(D|H_1) = 0.71$ and $P(D|H_2) = 0.705$. Bayesian equation then yields:

$$P = \frac{0.51 \times 0.71}{0.51 \times 0.71 + 0.49 \times 0.705} = 0.5117$$

If the probability obtained is greater than or equal to 0.5, the correlation method is used for calculating the error that is to be back-propagated to the profile-based neural network for weight adjustments.

For example if we obtain a prediction accuracy of 69% using the correlation method and a prediction accuracy of 72% using the committee method, then $P(D|H_1) = 0.69$ and $P(D|H_2) = 0.72$. Bayesian equation then yields:

$$P = \frac{0.51 \times 0.69}{0.51 \times 0.69 + 0.49 \times 0.72} = 49.93$$

If the probability obtained is less than 0.5, the committee method is used for calculating the error to be back-propagated for weight adjustments.

Similarly this new approach is tested using various values of probability for $P(H_1)$ and $P(H_2)$, and always choosing $P(H_1)$ greater than $P(H_2)$. From the several test cases, it is concluded that the values of 0.506 for $P(H_1)$ and 0.494 for $P(H_2)$ produce the greatest prediction accuracy. Using the Bayesian approach the prediction accuracy is obtained to be 73.3% (Q_3). This method produces the highest protein secondary structure prediction accuracy compared to all the other methods investigated in this research.

SIMULATION RESULTS

The simulations are performed using code written in JAVA on a 3.6 GHz Intel Pentium IV PC with hyper-threading running Microsoft Windows XP with 2GB of RAM and a 160GB hard disk. The multi-threading approach is used for running the GA and SA algorithms and the decision fusion methods in parallel. Table 1 provides the summary of the prediction accuracies achieved using various approaches in this research.

It is clearly evident from Table 1 that the Bayesian inference method improves the prediction accuracy by 2% compared to that of correlation method and

Table 1. Comparison of prediction accuracy (Q_3) for various approaches

| Approach Used | Prediction Accuracy (Q_3) |
|---|-------------------------------|
| Profile-based Neural Network | 66.8% |
| Profile-based Neural Network & GA | 69.2% |
| Profile-based Neural Network & SA | 68.3% |
| Decision fusion (Committee method) using Profile-based Neural Network | 70.8% |
| Decision fusion (Correlation method) using Profile-based Neural Network | 71.4% |
| Bayesian Inference method | 73.3% |

overall a prediction accuracy of 6.5% more than the profile-based neural network, which is a significant achievement.

FUTURE TRENDS

Many researchers all over the world are actively working on this problem using various methods to achieve at better prediction accuracy.

The future work can comprise the use of other decision fusion methods such as the clustering method, the fuzzy set method, and the probabilistic method for further improving on the protein secondary structure prediction accuracy.

CONCLUSION

This research aimed at improving the protein secondary structure prediction accuracy using the Bayesian inference method. Although there exists a variety of protein structure classification algorithms, research was performed in the belief that further improvement can be attained by finding the best way to combine several methods to lead to a unified better decision. From the results obtained we can conclude that applying AI algorithms along with decision fusion techniques improves the prediction accuracy compared to that of prediction by neural networks or AI algorithms individually or combined with profile-based neural networks. The simulations results prove that the Bayesian Inference method improves the prediction accuracy over the other decision fusion methods. The main advantage

of using this approach is that, it does not comprise the advantages provided by either committee or correlation methods of decision fusion.

KEY TERMS

Bayesian Inference: Bayesian inference is statistical inference in which evidence or observations are used to update or to newly infer the probability that a hypothesis may be true.

Decision Fusion: The process of combining classifiers is called decision fusion. Results from different methods, algorithms, sources or classifiers can often be combined (fused) to give estimates of a better quality than could be obtained from any of the individual sources alone.

Genetic Algorithm: Genetic Algorithms (GAs) are adaptive heuristic search algorithm premised on the evolutionary ideas of natural selection and genetic. The basic concept of GAs is designed to simulate processes in natural system necessary for evolution, specifically those that follow the principles first laid down by Charles Darwin of survival of the fittest. As such they represent an intelligent exploitation of a random search within a defined search space to solve a problem.

Neural Network: A Neural Network is an information processing paradigm that is inspired by the way biological nervous systems, such as the brain, process information. The key element of this paradigm is the novel structure of the information processing system. It is composed of a large number of highly interconnected processing elements (neurons) working in unison to solve specific problems.

Profile-Based Neural Network: This type of neural network configuration results when we feed the multiple alignments in the form of a sequence profile (for each position an amino acid frequency vector is fed to the network) instead of a base sequence to a neural network.

Protein: A large molecule composed of one or more chains of amino acids in a specific order determined by the base sequence of nucleotides in the DNA coding for the protein.

Secondary Structure: In biochemistry and structural biology, secondary structure is the general three-dimensional form of local segments of biopolymers such as proteins and nucleic acids (DNA/RNA).

Simulated Annealing Algorithm: Simulated annealing (SA) is a generic probabilistic meta-algorithm

for the global optimization problem, namely locating a good approximation to the global optimum of a given function in a large search space.

Prototype Based Classification in Bioinformatics

INTRODUCTION

Bioinformatics has become an important tool to support clinical and biological research and the analysis of functional data, is a common task in bioinformatics (Schleif, 2006). Gene analysis in form of micro array analysis (Schena, 1995) and protein analysis (Twyman, 2004) are the most important fields leading to multiple sub *omics*-disciplines like pharmacogenomics, glyco-proteomics or metabolomics. Measurements of such studies are high dimensional functional data with few samples for specific problems (Pusch, 2005). This leads to new challenges in the data analysis. Spectra of mass spectrometric measurements are such functional data requiring an appropriate analysis (Schleif, 2006). Here we focus on the determination of classification models for such data. In general, the spectra are transformed into a vector space followed by training a classifier (Haykin, 1999). Hereby the functional nature of the data is typically lost. We present a method which takes this specific data aspects into account. A wavelet encoding (Mallat, 1999) is applied onto the spectral data leading to a compact *functional* representation. Subsequently the Supervised Neural Gas classifier (Hammer, 2005) is applied, capable to handle functional metrics as introduced by Lee & Verleysen (Lee, 2005). This allows the classifier to utilize the functional nature of the data in the modelling process. The presented method is applied to clinical proteome data showing good results and can be used as a bioinformatics method for biomarker discovery.

BACKGROUND

Applications of mass spectrometry (ms) in clinical proteomics have gained tremendous visibility in the scientific and clinical community (Villanueva, 2004) (Ketterlinus, 2005). One major objective is the search for potential classification models for cancer studies, with strong requirements for validated signal patterns (Ransohoff, 2005). Primal optimistic results as given in (Petricoin, 2002) are now considered more carefully, because the complexity of the task of biomarker discovery and an appropriate data processing has been observed to be more challenging than expected (Ransohoff, 2005). Consequently the main recent work in this field is focusing on optimization and standardisation. This includes the biochemical part (e.g. Baumann, 2005), the measurement (Orchard, 2003) and the subsequently data analysis (Morris, 2005) (Schleif 2006).

PROTOTYPE BASED ANALYSIS IN CLINICAL PROTEOMICS

Here we focus on classification models. A powerful tool to achieve such models with high generalization abilities is available with the prototype based Supervised Neural Gas algorithm (SNG) (Villmann, 2002). Like all nearest prototype classifier algorithms, SNG heavily relies on the data metric d , usually the standard Euclidean metric. For high-dimensional data as they occur in proteomic patterns, this choice is not adequate due to two reasons: first, the functional nature of the data should be kept as far as possible. Second the noise present in the data set accumulates and likely disrupts the classification when taking a standard Euclidean

approach. A functional representation of the data with respect to the used metric and a weighting or pruning of especially (priorly not known) irrelevant function parts of the inputs, would be desirable. We focus on a functional distance measure as recently proposed in (Lee, 2005) referred as functional metric. Additionally a feature selection is applied based on a statistical pre-analysis of the data. Hereby a discriminative data representation is necessary. The extraction of such discriminant features is crucial for spectral data and typically done by a parametric peak picking procedure (Schleif, 2006). This peak picking is often spot of criticism, because peaks may be insufficiently detected and the functional nature of the data is partially lost. To avoid these difficulties we focus on a wavelet encoding. The obtained wavelet coefficients are sufficient to reconstruct the signal, still containing all relevant information of the spectra, but are typically more complex and hence a robust data analysis approach is needed. The paper is structured as follows: first the bioinformatics methods are presented. Subsequently the clinical data are described and the introduced methods are applied in the analysis of the proteome spectra. The introduced method aims on a replacement of the classical three step procedure of denoising, peak picking and feature extraction by means of a compact wavelet encoding which gives a more natural representation of the signal.

BIOINFORMATIC METHODS

The classification of mass spectra involves in general the two steps peak picking to locate and quantify positions of peaks and feature extraction from the obtained peak list. In the first step a number of procedures as baseline correction, denoising, noise estimation and normalization are applied in advance. Upon these prepared spectra the peaks have to be identified by scanning all local maxima. The procedure of baseline correction and recalibration (alignment) of multiple spectra is standard, and has been done here using ClinProTools (Ketterlinus, 2006). As an alternative we propose a feature extraction procedure preserving all (potentially small) peaks containing relevant information by use of the discrete wavelet transformation (DWT). The DWT has been done using the Matlab Wavelet-Toolbox (see <http://www.mathworks.com>). Due to the local analysis property of wavelet analysis the features can still be related back to original mass position in the spectral

data which is essential for further biomarker analysis. For feature selection the Kolmogorov-Smirnoff test (KS-test) (Sachs, 2003) has been applied. The test was used to identify features which show a significant ($p < 0.01$) discrimination between the two groups (cancer, control). In (Waagen, 2003) also a generalization to a multiclass experiment is given. The now reduced data set has been further processed by SNG to obtain a classification model with a *small* ranked set of features. The whole procedure has been cross-validated in a 10-fold cross validation.

WAVELET TRANSFORMATION IN MASS SPECTROMETRY

Wavelets have been developed as powerful tools (Rieder, 1998) used for noise removal and data compression. The discrete version of the continuous wavelet transform leads to the concept of a multi-resolution analysis (MRA). This allows a fast and stable wavelet analysis and synthesis. The analysis becomes more precise if the wavelet shape is adapted to the signal to be analyzed. For this reason one can apply the so called bi-orthogonal wavelet transform (Cohen, 1992), which uses two pairs of scaling and wavelet functions. One is for the decomposition/analysis and the other one for reconstruction/synthesis, giving a higher degree of freedom for the shape of the scaling and wavelet function. In our analysis such a smooth synthesis pair was chosen. It can be expected that a signal in the time domain can be represented by a small number of a relatively large set of coefficients from the wavelet domain. The spectra are reconstructed in dependence of a certain approximation level L of the MRA. The denoised spectrum looks similar to the reconstruction as depicted in Figure 1.

One obtains approximation- and detail-coefficients (Cohen, 1992). The approximation coefficients describe a generalized peak list, encoding primal spectral information. For linear MALDI-TOF spectra a device resolution of 500–800 Da can be expected. This implies limits to the minimal peak width in the spectrum and hence, the reconstruction level of the Wavelet-Analysis should be able to model corresponding peaks. A level $L = 4$ is appropriate for our problem (see Figure 1). Applying this procedure including the KS-test on the spectra with an initial number of 22306 measurement points per spectrum one obtains 602 wavelet coefficients

Figure 1. Wavelet reconstruction of the spectra with $L = 4, 5$, x-mass positions, y-arbitrary unit. Original signal - solid line. One observes for $L = 5$ (right plot) the peak approximate is to rough.

used as representative features per spectrum, still allowing a reliable functional representation of the data. The coefficients were used to reconstruct the spectra and the final functional representation of the signal.

PROTOTYPE CLASSIFIERS

Supervised Neural Gas (SNG) is considered as a representative for prototype based classification approaches as introduced by Kohonen (Kohonen, 1995). Different prototype classifiers have been proposed so far (Kohonen, 1995) (Sato, 1996) (Hammer, 2005) (Villmann, 2002) as improvements of the original approach. The SNG has been introduced in (Villmann, 2002) and combines ideas from the Neural Gas algorithm (NG) introduced in (Martinetz, 1993) with the Generalized learning vector quantizer (GLVQ) as given in (Sato, 1996).

Subsequently we give some basic notations and remarks to the integration of alternative metrics into Supervised Neural Gas (SNG). Details on SNG including convergence proofs can be found in (Villmann, 2002). Let us first clarify some notations: Let c_v in L be the label of input \mathbf{v} , L a set of labels (classes). Let V in \mathbb{R}^{DV} be a finite set of inputs \mathbf{v} . LVQ uses a fixed number of prototypes (weight vectors, codebook vectors) for each class. Let $\mathbf{W} = \{\mathbf{w}_r\}$ be the set of all codebook vectors and c_r be the class label of \mathbf{w}_r . Furthermore, let $\mathbf{W}_c = \{\mathbf{w}_r / c_r = c\}$ be the subset of prototypes assigned to class c in L . The task of vector quantization is realized by the map Ψ as a winner-take-all rule, i.e. a stimulus vector \mathbf{v} in V is mapped onto that prototype \mathbf{s} the pointer \mathbf{w}_s of which is closest to the presented stimulus vector \mathbf{v} , measured by a distance $d_\lambda(\mathbf{v}, \mathbf{w})$. $d_\lambda(\mathbf{v}, \mathbf{w})$ is an arbitrary differentiable similarity measure

which may depend on a parameter vector λ . For the moment we take λ as fixed. The neuron $\mathbf{s}(\mathbf{v})$ is called winner or best matching unit. If the class information of the weight vector is used, the above scheme generates decision boundaries for classes (details in (Villmann, 2002)). A training algorithm should adapt the prototypes such that for each class c in L , the corresponding codebook vectors \mathbf{W}_c represent the class as accurately as possible. Detailed equations and cost function for SNG are given in (Villmann, 2002). Here it is sufficient to keep in mind that in the cost function of SNG the distance measure can be replaced by an arbitrary (differentiable) similarity measure, which finally leads to new update formulas for the gradient descent based prototype updates.

Incorporation of a functional metric to SNG As pointed out before, the similarity measure $d_\lambda(\mathbf{v}, \mathbf{w})$ is only required to be differentiable with respect to λ and \mathbf{w} . The triangle inequality has not to be fulfilled necessarily (Hammer, 2005). This leads to a great freedom in the choice of suitable measures and allows the usage of non-standard metrics in a natural way. For spectral data, a functional metric would be more appropriate as given in (Lee, 2005). The obtained derivations can be plugged into the SNG equations leading to SNG with a functional metric, whereby the data are functions represented by vectors and, hence, the vector dimensions are spatially correlated. Common vector processing does not take this spatial order of the coordinates into account. As a consequence, the functional aspect of spectral data is lost. For proteome spectra the order of signal features (peaks) is due to the nature of the underlying biological samples and the measurement procedure. The masses of measured chemical compounds are given ascending and peaks encoding chemical structures with a higher mass follow chemical structures with lower masses.

In addition, multiple peaks with different masses may encode parts of the same chemical structure and, hence, are correlated. Lee proposed an appropriate norm with a constant sampling period τ :

$$\mathcal{L}_p^{fc}(\mathbf{v}) = \left(\sum_{k=1}^D (A_{k-1}(\mathbf{v}) + A_{k+1}(\mathbf{v}))^p \right)^{\frac{1}{p}}$$

with

$$A_k(\mathbf{v}) = \begin{cases} \frac{\tau}{2} |v_k| & \text{if } 0 \leq v_k v_{k-1} \\ \frac{\tau}{2} \frac{|v_k|}{|v_k| + |v_{k-1}|} & \text{if } 0 > v_k v_{k-1} \end{cases} \quad B_k(\mathbf{v}) = \begin{cases} \frac{\tau}{2} |v_k| & \text{if } 0 \leq v_k v_{k+1} \\ \frac{\tau}{2} \frac{|v_k|}{|v_k| + |v_{k+1}|} & \text{if } 0 > v_k v_{k+1} \end{cases}$$

are respectively of the triangles on the left and right sides of x_i . Just as for L_p , the value of p is assumed to be a positive integer. At the left and right ends of the sequence, x_0 and x_D are assumed to be equal to zero. The derivatives for the functional metric taking $p = 2$ are given in (Lee, 2005). Now we consider the scaled functional norm where each dimension $(0, 1]$, v_i is scaled by a parameter $\lambda_i > 0$ and all λ_i sum up to 1:

$$\mathcal{L}_p^{fc}(\lambda \mathbf{v}) = \left(\sum_{k=1}^D (A_{k-1}(\lambda \mathbf{v}) + A_{k+1}(\lambda \mathbf{v}))^p \right)^{\frac{1}{p}} \quad (9)$$

with

$$A_k(\lambda \mathbf{v}) = \begin{cases} \frac{\tau}{2} \lambda_k |v_k| & \text{if } 0 \leq v_k v_{k-1} \\ \frac{\tau}{2} \frac{\lambda_k |v_k|}{\lambda_k |v_k| + \lambda_{k-1} |v_{k-1}|} & \text{else} \end{cases} \quad B_k(\lambda \mathbf{v}) = \begin{cases} \frac{\tau}{2} \lambda_k |v_k| & \text{if } 0 \leq v_k v_{k+1} \\ \frac{\tau}{2} \frac{\lambda_k |v_k|}{\lambda_k |v_k| + \lambda_{k+1} |v_{k+1}|} & \text{else} \end{cases} \quad (10)$$

The prototype update changes to:

$$\frac{\partial \delta_k^2(\mathbf{x}, \mathbf{y}, \lambda)}{\partial x_k} = \frac{\tau^2}{2} (2 - U_{k-1} - U_{k+1}) (V_{k-1} + V_{k+1}) \Delta_k$$

with

$$U_{k-1} = \begin{cases} 0 & \text{if } 0 \leq \Delta_k \Delta_{k-1} \\ \left(\frac{\lambda_{k-1} \Delta_{k-1}}{\lambda_k |\Delta_k| + \lambda_{k-1} |\Delta_{k-1}|} \right)^2 & \text{else} \end{cases}, \quad U_{k+1} = \begin{cases} 0 & \text{if } 0 \leq \Delta_k \Delta_{k+1} \\ \left(\frac{\lambda_{k+1} \Delta_{k+1}}{\lambda_k |\Delta_k| + \lambda_{k+1} |\Delta_{k+1}|} \right)^2 & \text{else} \end{cases}$$

$$V_{k-1} = \begin{cases} 1 \lambda_k & \text{if } 0 \leq \Delta_k \Delta_{k-1} \\ \frac{\lambda_k |\Delta_k|}{\lambda_k |\Delta_k| + \lambda_{k-1} |\Delta_{k-1}|} & \text{else} \end{cases}, \quad V_{k+1} = \begin{cases} 1 \lambda_k & \text{if } 0 \leq \Delta_k \Delta_{k+1} \\ \frac{\lambda_k |\Delta_k|}{\lambda_k |\Delta_k| + \lambda_{k+1} |\Delta_{k+1}|} & \text{else} \end{cases}$$

And $\Delta_k = x_k - y_k$ using this parameterization one can emphasize/neglect different parts of the function for classification.

ANALYSIS OF PROTEOMIC DATA

The proposed data processing scheme is applied to clinical ms spectra taken from a cancer study (45 cancer, 50 control samples). Sample preparation and profile spectra analysis were carried out using the CLINPROT system (Bruker Daltonik, Bremen, Germany [BDAL]). The preprocessed set of spectra and the corresponding wavelet coefficients are then analyzed using the SNG

extended by a functional metric. We reconstructed the spectra based upon the discriminative wavelet coefficients determined by the Kolmogorov-Smirnoff test as explained above and used corresponding intensities as features. We used all features for the parameterized functional norm i.e. all $\lambda_i = 1$. The original signal with approx. 22000 sampling points had been processed with only 600 remaining points still encoding the significant parts of the signal relevant for discrimination between the classes. The SNG classifier with functional metric obtains a crossvalidation accuracy of 84% using functional metric and 82% by use of standard Euclidean metric. The results from the wavelet processed spectra are slightly better than using standard peak lists, with 81% crossvalidation accuracy.

FUTURE TRENDS

The proposed method generates a compact but still complex functional representation of the spectral data. While the bior3.7 wavelet gives promising results they are still not optimal, due to signal oscillations, leading to negative intensities in the reconstruction. Further, the functional nature of the data motivates the usage of a functional data representation and similarity calculation but there are also spectra regions encoded which do not contain meaningful biological information but measurement artefacts. In principle it should be possible to remove this overlaying artificial function from the real signal. Further it could be interesting to incorporate additional knowledge about the peak width, which is increasing over the mass axis.

CONCLUSION

The presented interpretation of proteome data demonstrate that the functional analysis and model generation using SNG with functional metric in combination with a wavelet based data pre-processing provides an easy and efficient detection of classification models. The usage of wavelet encoded spectra features is especially helpful in detection of small differences which maybe easily ignored by standard approaches as well as to generate a significant reduced number of points needed in further processing steps. The signal must not be shrunk to peak lists but could be preserved in its functional representation. SNG was able to process

high-dimensional functional data and shows good regularization. By use of the Kolmogorov-Smirnoff test we found a ranking of the features related to mass positions in the original spectrum which allows for identification of most relevant feature dimensions and to prune irrelevant regions of the spectrum. Alternatively one could optimize the scaling parameters of the functional norm directly during classification learning by so called relevance learning as shown in (Hammer, 2005) for scaled Euclidean metric. Conclusively, wavelet spectra encoding combined with SNG and a functional metric is an interesting alternative to standard approaches. It combines efficient model generation with automated data pre-treatment and intuitive analysis.

KEY TERMS

Bioinformatics: Generic term of a research field as well as a set of methods used in computational biology or medicine to analyse multiple kinds of biological or clinical data. It combines the disciplines of computer science, artificial intelligence, applied mathematics, statistics, biology, chemistry and engineering in the field of biology and medicine. Typical research subjects are problem adequate data pre-processing of measured biological sample information (e.g. data cleaning, alignments, feature extraction), supervised and unsupervised data analysis (e.g. classification models, visualization, clustering, biomarker discovery) and multiple kinds of modelling (e.g. protein structure prediction, analysis of expression of gene, proteins, gene/protein regulation networks/interactions) for one or multidimensional data including time series. Thereby the most common problem is the high dimensionality of the data and the small number of samples which in general make standard approach (e.g. classical statistic) inapplicable.

Biomarker: Mainly in clinical research one goal of experiments is to determine patterns which are predictive for the presents or prognosis of a disease state, frequently called biomarker. Biomarkers can be single or complex (pattern) indicator variables taken from multiple measurements of a sample. The ideal biomarker has a high sensitivity, specificity and is reproducible (under standardized conditions) with respect to control experiments in other labs. Further it can be expected that the marker is vanishing or changing during a treatment of the disease.

Clinical Proteomics: Proteomics is the field of research related to the analysis of the proteome of an organism. Thereby, clinical proteomics is focused on research mainly related to disease prediction and prognosis in the clinical domain by means of proteome analysis. Standard methods for proteome analysis are available by Mass spectrometry.

Mass Spectrometry: An analytical technique used to measure the mass-to-charge ratio of ions. In clinical proteomics mass spectrometry can be applied to extract fingerprints of samples (like blood, urine, bacterial extracts) whereby semi-quantitative intensity differences between sample cohorts may indicate biomarker candidates

Prototype Classifiers: Are a specific kind of neural networks and related to the kNN classifier. The classification model consists of so called prototypes which are representatives for a larger set of data points. The classification is done by a nearest neighbour classification using the prototypes. Nowadays prototype classifiers can be found in multiple fields (robotics, character recognition, signal processing or medical diagnosis) trained to find (non)linear relationships in data.

Relevance Learning: A method, typically used in supervised classification, to determine problem specific metric parameter. With respect to the used metric and learning schema univariate, correlative and multivariate relations between data dimensions can be analyzed. Relevance learning typically leads to significantly improved, problem adapted metric parameters and classification models.

Wavelet Analysis: Method used in signal processing to analyse a signal by means of frequency and local information. Thereby the signal is encoded in a representation of wavelets, which are specific kinds of mathematical functions. The Wavelet encoding allows the representation of the signal at different resolutions, the coefficients contain frequency information but can also be localized in the signal.

Randomized Hough Transform

Helsinki University of Technology, Finland

INTRODUCTION

Proposed in 1962, the Hough transform (HT) has been widely applied and investigated for detecting curves, shapes, and motions in the fields of image processing and computer vision. However, the HT has several shortcomings, including high computational cost, low detection accuracy, vulnerability to noise, and possibility of missing objects. Many efforts target at solving some of the problems for decades, while the key idea remains more or less the same. Proposed in 1989 and further developed thereafter, the Randomized Hough Transform (RHT) manages to considerably overcome these shortcomings via innovations on the fundamental mechanisms, with random sampling in place of pixel scanning, converging mapping in place

of diverging mapping, and dynamic storage in place of accumulation array. This article will provide an overview on advances and applications of RHT in the past one and half decades.

BACKGROUND

Taking straight line detection as an example, the upper part of Fig. 1 shows the key idea of the Hough Transform (HT) (Hough, 1962). A set of points on a line $y=kx+b$ in the image are mapped into a set of lines across a point (k, b) in the parameter space. A uniform grid is located on a window in the (k, b) space, with an accumulator $a(k, b)$ at each bin. As each point (x, y) on the image is mapped into a line in the (k, b) space, every associated accumulator $a(k, b)$ is incremented by 1. We can detect

Figure 1. From hough transform to randomized hough transform

lines by finding every accumulator with its score $a(k, b)$ larger than a given threshold.

The Hough Transform was brought to the attention of the mainstream image processing community by Rosenfeld (1969). Then Duda and Hart (1972) not only introduced the polar parameterization technique for more efficient line detection, but also demonstrated how a circle can be detected. Kimme, Ballard and Sklansky (1975) made circular curve detection significantly more effective by using the gradient information of pixels. Merlin and Faber (1975) showed how the HT could be generalized to detect an arbitrary shape at a given orientation and a given scale. Ballard (1981) eventually generalized the HT to detect curves of a given arbitrary shape for any orientation and any scale. Since then, a lot of applications, variants and extensions of the HT have been published in the literature. A survey on these developments of the HT is given by Illingworth and Kittler (1988).

However, the HT has several critical drawbacks as follows:

- a. All pixels are mapped, and every bin in the grid needs an accumulator. If there are d parameters, each represented by M bins or grid points, one needs M^d accumulators.
- b. To reduce the computational cost, quantization resolution cannot be high, which blurs the peaks and leads to low detection accuracy.
- c. Each pixel activates every accumulator located on a line, but there is only one that represents the correct one while all the others are disturbances.
- d. If the grid window is set inappropriately, some objects may locate outside the window and thus cannot be detected.
- e. Disturbing and noisy pixels cause many interfering accumulations.

Many efforts have been made to alleviate these problems. Using the gradient information of pixels is one of them. Another is analyzing noise and error sensitivity (van Veen, 1981; Brown, 1983; Grimson & Huttenlocher, 1990). The third is the use of hierarchical voting accumulation (Li, Lavin & LeMaster, 1986) or multiresolution (Atiquzzaman, 1992). Yet another is improving the effect of quantization through the use of kernels (Palmer, Petrou, & Kittler, 1993) or error propagation analysis (Ji & Haralick, 2001), as well as hypothesis testing (Princen, Illingworth, & Kittler,

1994). However, none of these suggestions offer any fundamental changes to the key mechanisms of HT.

Proposed in 1989 and further investigated thereafter (Xu, Oja, & Kultanen, 1990; Xu & Oja, 1993), the Randomized Hough Transform (RHT) tackles the above problems by using a fundamental innovation: the one-to-many diverging mapping from the image space to the parameter (accumulator) space, as shown in the upper part of Fig. 1(a), is replaced by a many-to-one converging mapping, as shown in the bottom part of Fig. 1(a). This fundamental change further enables several joint improvements, such as a random sampling in place of pixel scanning, a small size dynamic storage in place of the array of M^d accumulators, and an adaptive detection in place of enumerating all the pixels and picking those accumulators with scores larger than a threshold. As a result, not only time and storage complexity have been reduced significantly, but also the detection accuracy has been improved considerably.

Subsequently, many studies have been made on RHT. On one hand, there are various real applications such as medical images (Behrens, Rohr, & Siegfried, 2003), range images (Ding, et al, 2005), motion detection (Heikkonen, 1995), object tracking for a mobile robot (Jean & Wu, 2004), soccer robot (Claudia, Rous, & Kraiss, 2004), mine detection (Milisavljevic, 1999), and others (Chutatape & Guo, 1999). On the other hand, there are also many further developments on RHT, including an efficient parameterization for ellipse detection (McLaughlin, 1998), extension to motion detections (Kalviainen, Oja, & Xu, 1991; Xu, 2007), the uses of local gradient information, local connectivity and neighbor-orientation for further improvements (Brailovsky, 1999; Kalviainen & Hirvonen, 1997), an integration with error propagation analysis (Ji & Xie, 2003), a modification of random sampling to importance sampling (Walsha & Raftery, 2002), and others (Xu, 2007). Due to space limit, it is not possible to provide a complete survey here. An early review on RHT variants is referred to (Kalviainen, Hirvonen, Xu, & Oja, 1995), and recent elaborations on RHT are referred to (Xu, 2007).

It may also need to be mentioned that the literature on RHT studies often includes studies under the name of probabilistic HT (Bergen & Shvaytser, 1991; Kiryati, Eldar & Bruckstein, 1991) that also suggests to use a random sampling to replace the scanning in the implementation of the standard HT and thus shares one

of the previously mentioned RHT features. However, it will not lose too much generality to regard it as a degenerated case of RHT for an understanding purpose, though there are some detailed differences.

BASIC RHT MECHANISMS AND CHARACTERISTICS

As shown in Fig.1, one pixel is mapped into all the points on a line passing (k, b) by the diverging mapping mechanism of HT, which actually incurs the above drawbacks (a)-(e). RHT replaces this mechanism with a converging mapping mechanism such that two or more pixels are picked to jointly determine a line, i.e., mapped into one point (k, b) . By this mechanism, different points on the same line $y=kx+b$ will hit the same point (k, b) , without creating a great number of false accumulations. Also, the feature of being mapped

into one point at a time makes it possible to construct accumulators dynamically, with no need of laying a grid on a pre-specified window. We only need to accumulate $a(k, b)$ at those locations activated by the converging mappings. Also, quantization resolution may vary for different locations, and each quantization bin can be replaced by a kernel. As a result, the drawbacks (b),(c),(d) no longer exist.

Without considering the quantization effect, if there is a line consisting of n pixels on an image, we get a peak with n counts in its accumulated scores. Assume that in its neighbour there is another peak of false line consisting of $m < n$ pixels, then the ratio n/m describes a signal/noise ratio of a reliable detection by HT. In RHT, assuming that we exhaust all the possible pairs of pixels, the voting counts for the line will be $n(n-1)/2$ while the voting counts for the disturbing false line will be $m(m-1)/2$, i.e., the signal/noise ratio becomes $\frac{n(n-1)}{m(m-1)}$ that is $\frac{n-1}{m-1}$ times increased compared

Table 1. Missing probability versus false alarm probability

| THE DETECTING RULE | |
|--|---|
| On an image that consists of N pixels Detect a point $\theta \in \Theta$ as a line if it is hit by more than k_0 times. | |
| MISSING PROBABILITY | FALSE-ALARM PROBABILITY |
| Consider a line consisting of n pixels, a trial of randomly sampling two pixels has a probability $p_c = \frac{n(n-1)}{N(N-1)}$ that both pixels come from the line, i.e., the line is successfully hit in the parameter space by a probability p_c . After M trials, the number of being successfully hit is a variable ξ in a binomial distribution, $p_c(\xi=k) = C_M^k p_c^k (1-p_c)^{M-k}$ see eqn.(4b) in (Xu & Oja, 1993). A risk of missing this line by the detecting rule has a probability $P_{miss} = \sum_{k=0}^{k_0} p_c(\xi=k)$ controlling it below a pre-specified rate, we can determine a lower bound $M > M_c.$ | Consider a false line consisting of m pixels, a trial of randomly sampling two pixels has a probability $p_r = \frac{m(m-1)}{N(N-1)}$ that both pixels come from the line, i.e., the line is successfully hit in the parameter space by a probability p_r . After M trials, the number that it is hit is a variable ξ in a binomial distribution too, $p_r(\xi=k) = C_M^k p_r^k (1-p_r)^{M-k}$ In this case, taking a point $\theta \in \Theta$ that is hit by more than k_0 times as a line has a risk of taking a false line as a solution with a probability $P_{false} = 1 - \sum_{k=0}^{k_0} p_r(\xi=k)$ controlling it below a pre-specified rate, we can determine an upper bound $M < M_r.$ |

to HT. Thus, the above problem (e) can also be significantly improved.

In fact, it is not necessary to exhaust all the possible pairs of pixels for RHT to detect lines. Via randomly sampling two pixels for a converging mapping, we only need to have a small fraction of all the possible pairs to get the degree $\frac{n(n-1)}{m(m-1)}$ with a high probability, which solves the above problem (a) with a significant reduction in both time and space complexities. A more precise explanation is given in Tab.1. We detect a point $\theta \in \Theta$ as a line if it is hit by more than k_0 times, with a risk of missing this line by a small probability P_{miss} . Controlling it below a pre-specified rate, we need to only run $M > M_c$ trails. On the other hand, controlling probability η_r of taking a false line as a solution, we can determine an upper bound $M < M_r$. Even if a line is falsely detected, it can be later discarded by evaluating all the detected lines via the actual pixels on the image. Thus, a large η_r will not affect the performance too much, but will only waste computing time.

RHT GENERAL FORM AND EXTENSIONS

In general, RHT is applicable to a curve that can be expressed in a parametric equation $f(x,y,\theta) = 0$ with a number κ of free parameters. Solving the joint equations $f(x_i, y_i, \theta) = 0, i = 1, \dots, \kappa$ yields a converging mapping into a point $\theta \in \Theta$. A general algorithmic form is given in Tab.2.

We can obtain variants and extensions by modifying either one or more of the first four steps in Tab.2. First, the converging mapping in Step 1 can be altered by varying either the way of getting samples, or the way of computing $\theta \in \Theta$ from these samples, or both. Instead of random sampling, samples can be obtained by searching a candidate solution in S_0 via local connectivity and neighbor-orientation (Kalviainen, Hirvonen, Xu, & Oja, 1995; Brailovsky, 1999; Kalviainen & Hirvonen, 1997) or by importance sampling (Walsha & Raftery, 2002). Instead of solving joint equations,

Table 2. The general RHT in algorithmic form

Given k_0 and computing M_c as in Tab.1. Let the set of candidate curves S_θ be initially empty and set a pre-specified number k_θ for the number of candidate curves.

Step 1: Randomly sample a number of pixels and implement a converging mapping into a point $\theta \in \Theta$.

Step 2: Check whether there is already an accumulator $\alpha(\tilde{\theta})$ with

$\theta = \tilde{\theta}$ or $\tilde{\theta} \in N_\theta$, where N_θ denotes a neighbourhood of θ :

- if yes, set $\alpha(\theta^{new}) = \alpha(\tilde{\theta}) + 1$, $\theta^{new} = \alpha\theta + (1-\alpha)\tilde{\theta}$, $\alpha > 0$ and delete the old $\alpha(\tilde{\theta})$,
- otherwise, set $\alpha(\theta^{new}) = 1$.

Step 3: Check all the accumulators, if there is one $\alpha(\theta) > k_0$, then put the corresponding θ into S_θ as a candidate solution;

Step 4: If the number of candidate solutions in S_θ is larger than k_θ , examine every candidate $\theta \in S_\theta$ to see whether there are enough image pixels that can be reasonably expressed by θ

- if yes, refine θ by these pixels as a confirmed solution and then remove the pixels from the image;
- otherwise, simply discard this θ .

Step 5: $t \leftarrow t+1$ if $t > M_c$, then stop; otherwise go to Step 1.

as discussed in (Xu, 2007), a solution can also be obtained by either a least square fitting, an L_p norm fitting, or by maximum likelihood estimation. Sometimes, it may even consider under-constrained equations by taking less samples, from which a parametric curve or surface in Θ is obtained to implement an array based accumulation similar to HT.

Second, there are also alternatives for Step 2 and Step 3. One extreme is returning to an array based accumulation. The other extreme is that all the mapped points in Θ are stored as they are, and either cluster analysis or kernel based density estimation is made on them to find cluster centres and density degrees for detecting curves or objects. Between the two extremes, we may consider a trade off or their combination (Xu, 2007). Third, Step 4 can also be performed with different choices, including a δ -band test, a fitting error threshold, and a hypothesis testing (Xu, 2007).

Moreover, instead of checking candidate solution every time t , we can let the procedure run until $t = M_c$, put those accumulators with $a(\theta) > k_0$ into S_0 as candidate solutions and examine these candidates at Step 4. Also, checking and examining candidates can be made per a pre-specified period. Furthermore, gradient information in a grey image may also improve the converging mapping.

The last but not the least, RHT has also be extended to detect objects by a template as shown in Fig.2.

FUTURE TRENDS

Challenges to RHT mainly come from the effects of noise and quantization. Two types of noise are shown in Fig.3. The first type is in Fig.3(a) with disturbing pixels added but the original pixels unaffected. This noise type may reduce the signal/noise ratio, resulting in more computing time and space. However, the accuracy of the detected line will be not affected. The second type is in Fig.3(b), with some original pixels deviated from the exact line. The quantization effect can be regarded as a special case of this type that uniformly distributed noise is added to the coordinates of pixels. The second type not only reduces the signal/noise ratio but also makes the detected line inaccurate. As yet, there lacks a systematic theoretical analysis on how the solution accuracy will be affected by this second type. More importantly, theoretical guides are lacking on how to control the accuracy of detected curves and objects.

The tasks of detecting curves and objects can also be performed from the perspective of mixture based learning, which is much more robust in the case of the second type of noise (Xu, 2003; Liu, Qiao, & Xu, 2006; Xu, 2007). Solving pattern recognition tasks by machine learning approaches is a popular trend in the past decade and currently. Actually, the machine learning perspective are complementary to the perspective

Figure 2. Use a template to match a shape via translation μ , rotation ϕ and scaling λ

Figure 3. Different effects by two types of noises

of HT/RHT type evidence accumulation. A trend is integrating the strengths of both.

CONCLUSION

This article provides not only a brief overview on nearly two decade developments and applications of RHT for detecting curves, shapes, and motions, but also a tutorial and re-elaboration on basic mechanisms, variants, and extensions of RHT, as well as challenges and future trends of RHT studies. Recently, a general problem solving paradigm has been developed and implemented by an integration of five essential mechanisms (Xu, 2007). Not only the difference between the machine learning perspective and HT/RHT perspective can be understood via handling two coupled core tasks, namely amalgamating evidences and discriminating differences, but also different implementations of these mechanisms and differences in a specific integration may bring us new results and potential directions for future studies.

KEY TERMS

δ Band Test: A pixel is said to fall in the δ band of ρ (it denotes a curve or surface) in the image space if the shortest distance from this pixel to ρ is less than a pre-specified threshold δ . Pixels falling in the δ band of ρ are regarded as belonging to ρ , and a δ band test can be designed according to these pixels.

Cluster Analysis: Beyond using an accumulation array, in the cases of a converging mapping, every mapped point in R^k is memorized. After an enough number of converging mappings, we get a set of points on which cluster analyses can be made to find clusters' centre (mean or median).

Diverging Mapping vs. Converging Mapping:

Given pixels of a number m , a set of under-constrained equations specify a curve or manifold of a dimension $\geq k - m$ in R^k if $m < k$. E.g., from a line $y=kx+b$ passing a given pixel in the image, we have a line $b=y-kx$ in R^2 . This case is called diverging mapping because m pixels are mapped diversely to the R^k space. On the other hand, if $m \geq k$, a unique point in the R^k space maybe determined by solving a set of joint equations or optimizing a cost when the joint equations are over-constrained, i.e., we have a converging mapping that maps m pixels into one point in R^k .

Kernel Estimator: Every mapped point is memorized as the centre of a kernel function, e.g., a bell-shaped such as a Gaussian. Collectively, mapped points forms a density estimation for a multi-mode distribution, with each mode in place of the above cluster centre.

Random Sampling: Given a set of N pixels, we take a number m of pixels with each picked randomly with a probability $1/N$. Repeating this sampling by an enough number of times, a global configuration of N pixels will emerge, without enumerating all the N pixels.

Threshold Based Voting vs. Local Maxima Finding:

Given a pre-specified threshold, an accumulator in an array is picked if it receives votes larger than the threshold, without considering any neighborhood. Finding a local maximum means to find an accumulator with its votes larger than those of accumulators located in its neighborhood area.

Under-Constrained vs. Over-Constrained Equations:

For a parametric equation of k free parameters, we have a set of under-constrained equations with pixels of a number $m < k$ and a set of over-constrained equations with pixels of a number $m \geq k$ in a non-degenerate way.

Ranking Functions

Franz Huber

California Institute of Technology, USA

INTRODUCTION

Ranking functions have been introduced under the name of ordinal conditional functions in Spohn (1988; 1990). They are representations of epistemic states and their dynamics. The most comprehensive and up to date presentation is Spohn (manuscript).

BACKGROUND

The literature on knowledge, belief, and uncertainty in artificial intelligence is divided into two broad classes. In epistemic logic (Hintikka 1961, Halpern & Fagin & Moses & Vardi 1995), belief revision theory (Alchourrón & Gärdenfors & Makinson 1985, Gärdenfors 1988, Rott 2001), and nonmonotonic reasoning (Kraus & Lehmann & Magidor 1990, Makinson 2005) qualitative approaches are used to represent the epistemic state of an agent. In probability theory (Pearl 1988, Jeffrey 2004) and alternatives (Dempster 1968, Shafer 1976, Dubois & Prade 1988) epistemic states are represented quantitatively as degrees of belief rather than yes-or-no beliefs (see Halpern 2003 for an overview). One of the distinctive features of ranking functions is that they are quantitative, but nevertheless induce a notion of yes-or-no belief that satisfies the standard requirements of rationality, viz. consistency and deductive closure.

RANKING FUNCTIONS

Let W be a non-empty set of possibilities or worlds, and let \mathbf{A} be a field of propositions over W . That is, \mathbf{A} is a set of subsets of W that includes the empty set \emptyset ($\emptyset \in \mathbf{A}$) and is closed under complementation with respect to W (if $A \in \mathbf{A}$, then $W \setminus A \in \mathbf{A}$) and finite intersection (if $A \in \mathbf{A}$ and $B \in \mathbf{A}$, then $A \cap B \in \mathbf{A}$). A function ρ from the field \mathbf{A} over W into the natural numbers N extended by ∞ , $\rho: \mathbf{A} \rightarrow N \cup \{\infty\}$, is a (*finitely minimitive*) *ranking function* on \mathbf{A} if and only if for all propositions A, B in \mathbf{A} :

1. $\rho(W) = 0$
2. $\rho(\emptyset) = \infty$
3. $\rho(A \cup B) = \min\{\rho(A), \rho(B)\}$

If the field of propositions \mathbf{A} is closed under countable intersection (if $A_1 \in \mathbf{A}, \dots, A_n \in \mathbf{A}, \dots, n \in N$, then $A_1 \cap \dots \cap A_n \cap \dots \in \mathbf{A}$) so that \mathbf{A} is a σ -field, a ranking function ρ on \mathbf{A} is *countably minimitive* if and only if it holds for all propositions $A_1 \in \mathbf{A}, \dots, A_n \in \mathbf{A}, \dots$

4. $\rho(A_1 \cup \dots \cup A_n \cup \dots) = \min\{\rho(A_1), \dots, \rho(A_n), \dots\}$

If the field of propositions \mathbf{A} is closed under arbitrary intersection (if $\mathbf{B} \subseteq \mathbf{A}$, then $\cap \mathbf{B} \in \mathbf{A}$) so that \mathbf{A} is a γ -field, a ranking function ρ on \mathbf{A} is *completely minimitive* if and only if it holds for all sets of propositions $\mathbf{B} \subseteq \mathbf{A}$:

5. $\rho(\cup \mathbf{B}) = \min\{\rho(A): A \in \mathbf{B}\}$

A ranking function ρ on \mathbf{A} is *regular* just in case $\rho(A) < \infty$ for each non-empty or consistent proposition A in \mathbf{A} .

The conditional ranking function $\rho(\cdot|B): \mathbf{A} \times \mathbf{A} \rightarrow N \cup \{\infty\}$ based on the ranking function ρ on \mathbf{A} is defined such that for all propositions A, B in \mathbf{A} :

6. $\rho(A|B) = \rho(A \cap B) - \rho(B)$ if $A \neq \emptyset$, and $\rho(\emptyset|B) = \infty$

$\rho(\cdot|B)$ is a ranking function on \mathbf{A} , for each proposition B in \mathbf{A} .

A function κ from the set of worlds W into the natural numbers N , $\kappa: W \rightarrow N$, is a *pointwise ranking function* on W if and only if $\kappa(w) = 0$ for at least one world w in W . Each pointwise ranking function κ on W induces a regular and completely minimitive ranking function ρ_κ on every field of propositions \mathbf{A} over W by defining

7. $\rho_\kappa(A) = \min\{\kappa(w): w \in A\}$ ($= \infty$ if $A = \emptyset$)

Huber (2006) discusses under which conditions a ranking function on a field of propositions \mathbf{A} induces a pointwise ranking function on the underlying set of worlds W .

The rank of a proposition A , $\rho(A)$, represents the degree to which an agent with ranking function ρ disbelieves A . If $\rho(A) = 0$, the agent does not disbelieve A . However, this does not mean that she believes A . She may well suspend judgment and neither disbelieve A nor its complement or negation $W \setminus A$ (in this case $\rho(A) = \rho(W \setminus A) = 0$). Rather, belief in a proposition is characterized by disbelief in its negation: an agent with ranking function $\rho: \mathbf{A} \rightarrow N \cup \{\infty\}$ believes $A \in \mathbf{A}$ if and only if $\rho(W \setminus A) > 0$. The *belief set* Bel_ρ of an agent with ranking function $\rho: \mathbf{A} \rightarrow N \cup \{\infty\}$ is the set of all propositions she believes:

$$\text{Bel}_\rho = \{A \in \mathbf{A}: \rho(W \setminus A) > 0\}$$

The axioms of ranking theory require an agent to not disbelieve both a proposition and its negation – i.e. at least one of A , $W \setminus A$ has to be assigned rank 0. Thus an agent with ranking function $\rho: \mathbf{A} \rightarrow N \cup \{\infty\}$ believes $A \in \mathbf{A}$ if and only if $\rho(W \setminus A) > \rho(A)$. For a given $\rho: \mathbf{A} \rightarrow N \cup \{\infty\}$, this suggests to define the *belief function induced by* ρ , $\beta_\rho: \mathbf{A} \rightarrow Z \cup \{\pm\infty\}$, such that for all propositions A in \mathbf{A} :

$$\beta_\rho(A) = \rho(W \setminus A) - \rho(A)$$

β_ρ assigns positive numbers to the propositions that are believed, negative numbers to the propositions that are disbelieved, and 0 to those propositions and their negations with respect to which the agent suspends judgment. As a consequence,

$$\text{Bel}_\rho = \{A \in \mathbf{A}: \beta_\rho(A) > 0\}$$

Bel_ρ is consistent and deductively closed in the finite sense, for every ranking function ρ on \mathbf{A} . That is, $\cap \mathbf{B} \neq \emptyset$ for every finite $\mathbf{B} \subseteq \text{Bel}_\rho$; and $A \in \text{Bel}_\rho$ if there is a finite $\mathbf{B} \subseteq \text{Bel}_\rho$ such that $\cap \mathbf{B} \subseteq A$, for any $A \in \mathbf{A}$. If $\rho: \mathbf{A} \rightarrow N \cup \{\infty\}$ is countably/completely minimitive, Bel_ρ is consistent and deductively closed in the following countable/complete sense: $\cap \mathbf{B} \neq \emptyset$ for every countable/arbitrary $\mathbf{B} \subseteq \text{Bel}_\rho$; and $A \in \text{Bel}_\rho$ if there is a countable/arbitrary $\mathbf{B} \subseteq \text{Bel}_\rho$ such that $\cap \mathbf{B} \subseteq A$, for any $A \in \mathbf{A}$. As will be seen below, from a diachronic

point of view the converse is true as well. However, first we have to discuss how an epistemic agent is to update her ranking function when she learns new information.

UPDATE RULES

A theory of epistemic states is incomplete if it does not account for the way the epistemic states are updated when the agent receives new information. As there are different formats in which the agent may receive new information, there are different update rules. The simplest and most unrealistic case is that of the agent becoming certain of a new proposition. This case is covered by

Plain Conditionalization

If the agent's epistemic state at time t is represented by the ranking function ρ on \mathbf{A} , and if, between t and t' , the agent becomes certain of the proposition $E \in \mathbf{A}$ and of no logically stronger proposition $E+ \subset E$, $E+ \in \mathbf{A}$, then the agent's epistemic state at time t' should be represented by the ranking function $\rho' = \rho(\cdot|E)$ on \mathbf{A} .

We usually do not learn by becoming certain of a proposition, though. In most cases the new information merely changes the strength of our beliefs in various propositions. This is illustrated by a variation of an example due to Jeffrey (1983). Let our agent be interested in the color of the carpet of her hotel room. At time t , before checking in, she neither believes nor disbelieves any of the following three hypotheses: the carpet is beige (*beige*), the carpet is brown (*brown*), the carpet is black (*black*). However, she is certain that the carpet is either beige or brown or black. The relevant part of her ranking function at time t thus looks as follows: $\rho(\text{beige}) = \rho(\text{not beige}) = \rho(\text{brown}) = \rho(\text{not brown}) = \rho(\text{black}) = \rho(\text{not black}) = \rho(\text{beige or brown or black}) = 0$, $\rho(\text{neither beige nor brown nor black}) = \infty$.

At time t' , after checking in and when opening the door to her room, it appears to the agent that the carpet is rather dark. As a consequence she now believes that the carpet is either brown or black. But since it is late at night, the curtains are closed, and she has not turned on the light yet, she cannot tell whether the carpet is brown or black. Her ranks for the relevant propositions

thus change to the following values: $\rho'(beige) = \rho'(not\ brown) = \rho'(not\ black) = 1$, $\rho'(not\ beige) = \rho'(brown) = \rho'(black) = 0$.

A change in the strength of the agent's beliefs about the color of the carpet will affect the strength of her beliefs about the color of, say, the furniture in the hotel room. For instance, at time t , our agent is pretty confident that the hotel room does not have dark furniture if the carpet is brown – and similarly if the carpet is black. She is also pretty confident that the hotel room has dark furniture if the carpet is beige. The relevant part of her ranking function at time t looks as follows: $\rho(dark|brown) = \rho(dark|black) = 3$, $\rho(dark|beige) = 0$. This implies that, at time t , the agent neither believes the furniture is dark nor that it is not dark, $\rho(dark) = \rho(not\ dark) = 0$.

The important question now is how the agent should update the rest of her ranking function (including the ranks for the propositions about the color of the furniture) when her ranks for the propositions about the color of the carpet change as specified above. The answer, already formulated in Spohn (1988), is given by

Spohn Conditionalization

If the agent's epistemic state at time t is represented by the ranking function ρ on \mathbf{A} , and if, between t and t' , the agent's ranks on the partition $\{E_i \mid i \in I\}$ change to $n_i \mid i \in I$ with $\min_i n_i = 0$ ($n_i = 0$ if $E_i = W$ and $n_i = \infty$ if $E_i = \emptyset$), and the agent's finite ranks change on no finer partition, then the agent's epistemic state at time t' should be represented by the ranking function $\rho' = \min\{\rho(\cdot|E_i) + r_i, \dots, \rho(\cdot|E_n) + r_n, \dots\}$ on \mathbf{A} .

Applied to our example this means that, at time t' , the agent's rank for the proposition that the furniture is dark should be $\rho'(dark) = \min\{\rho(dark|beige) + 1, \rho(dark|brown) + 0, \rho(dark|black) + 0\} = 1$. That is, at time t' , the agent believes, if only very weakly, that the furniture is not dark.

Spohn Conditionalization covers Plain Conditionalization as a special case. Shenoy (1991) presents an update rule for evidence of a still different format.

JUSTIFICATION

Ranking theory tells an epistemic agent how to organize her beliefs, and how to update her beliefs when she receives new information of various formats. Why should the agent follow those prescriptions?

The answer to this question requires a bit of terminology. An agent's *degree of entrenchment* for the proposition A is the number of information sources providing the information A that it takes for the agent to give up her disbelief in A . If the agent does not disbelieve A to begin with, her degree of entrenchment for A is 0. If no finite number of information sources providing the information A makes the agent give up her disbelief in A , her degree of entrenchment for A is ∞ .

Degrees of entrenchment are used to measure an epistemic agent's degrees of disbelief. If you want to measure my degree of disbelief for the proposition that Madrid is the capitol of Spain, you put me on a busy plaza in the center of Madrid and count the number of people passing by and telling me that Madrid is the capitol of Spain. My degree of entrenchment for the proposition that Madrid is the capitol of Spain equals n just in case I stop disbelieving that Madrid is the capitol of Spain after n people have passed by and told me it is – provided all those people are independent and equally reliable, indeed minimally positively reliable. Most people (and certainly all people in Madrid) are more than minimally positively reliable, though. An agent's *degree of disbelief* in A is therefore defined as the number of information sources providing the information A that it would take for the agent to give up her disbelief that A if those information sources were independent and minimally positively reliable.

Now we can explain why an agent's degrees of disbelief should obey the ranking calculus and thus be ranks, and why she should update her ranks according to Spohn Conditionalization. She should do so because doing so is necessary and sufficient for her to always have consistent and deductively closed beliefs. More precisely, Huber (2007) proves the following.

Consistency Theorem

An agent's belief set is and will always be consistent and deductively closed in the finite/countable/complete sense (and possibly conditional on some evidential proposition) if and only if this agent's degree of disbelief function is a finitely/countable/completely minimitive

ranking function and the agent updates according to Plain/Spohn/Shenoy Conditionalization when she receives information of the appropriate format.

Seen this way, the axioms and update rules of ranking theory are nothing but a diachronic version of consistency and deductive closure.

FUTURE TRENDS

One question in artificial intelligence is how an agent should update her epistemic state if she learns new conceptual information without also learning anything factual about the world she lives in. There are several ways in which such a conceptual change may occur. The agent may learn a new concept as when an enological ignoramus learns the concept *barrique*. Or the agent may learn that she has omitted a possibility from her set of worlds as when an enological ignoramus learns that there are rosé wines besides red and white wines. All these conceptual changes involve the adoption of a new set of worlds W and, consequently, a new field of propositions \mathbf{A} on the side of the agent. None of these conceptual changes seems to be adequately modeled by any of the formalisms mentioned at the beginning. Ranking theory is able to adequately model those conceptual changes by employing the so called *ur* or *tabula rasa* ranking – i.e. that ranking function that assigns rank 0 to every proposition. If the agent adds new possibilities to her set of worlds she should simply assign rank 0 to all those new possibilities. Similarly in case the agent replaces the old worlds by richer worlds. Huber (2009) discusses this and other future trends.

CONCLUSION

Ranking functions are an indispensable tool for artificial intelligence. First, they seem to adequately model most if not all of those phenomena that are dealt with in both qualitative as well as quantitative approaches to uncertainty. Second, they provide a link between these two classes of approaches that has been missing so far. Third, they can deal with phenomena that neither qualitative nor quantitative approaches seem to be able to deal with.

KEY TERMS

Belief: An agent with ranking function $\rho: \mathbf{A} \rightarrow N \cup \{\infty\}$ believes A if and only if $\rho(W \setminus A) > 0$ – equivalently, if and only if $\rho(W \setminus A) > \rho(A)$.

Belief Set: The *belief set* of an agent with ranking function $\rho: \mathbf{A} \rightarrow N \cup \{\infty\}$ is the set of propositions the agent believes, $\text{Bel}_\rho = \{A \in \mathbf{A}: \rho(W \setminus A) > 0\}$.

Conditional Ranking Function: The *conditional ranking function* $\rho(\cdot|\cdot): \mathbf{A} \times \mathbf{A} \rightarrow N \cup \{\infty\}$ based on the ranking function ρ on \mathbf{A} is defined such that for all propositions A, B in \mathbf{A} : $\rho(A|B) = \rho(A \cap B) - \rho(B)$ if $A \neq \emptyset$, and $\rho(\emptyset|B) = \infty$.

Completely Minimative Ranking Function: A ranking function ρ on a γ -field of propositions \mathbf{A} is *completely minimative* if and only if $\rho(\cup \mathbf{B}) = \min\{\rho(A): A \in \mathbf{B}\}$ for each set of propositions $\mathbf{B} \subseteq \mathbf{A}$.

Countably Minimative Ranking Function: A ranking function ρ on a σ -field of propositions \mathbf{A} is *countably minimative* if and only if $\rho(A_1 \cup \dots \cup A_n \cup \dots) = \min\{\rho(A_1), \dots, \rho(A_n), \dots\}$ for all propositions $A_1 \in \mathbf{A}, \dots, A_n \in \mathbf{A}, \dots$

Pointwise Ranking Function: A function κ from the set of worlds W into the natural numbers N , $\kappa: W \rightarrow N$, is a *pointwise ranking function* on W if and only if $\kappa(w) = 0$ for at least one world w in W .

Degree of Disbelief: An agent's *degree of disbelief* in the proposition A is the number of information sources providing the information A that it would take for the agent to give up her disbelief that A if those information sources were independent and minimally positively reliable.

Degree of Entrenchment: An agent's *degree of entrenchment* for the proposition A is the number of information sources providing the information A that it takes for the agent to give up her disbelief in A .

Ranking Function: A function ρ on a field of propositions \mathbf{A} over a set of worlds W into the natural numbers extended by ∞ , $\rho: \mathbf{A} \rightarrow N \cup \{\infty\}$, is a (*finitely minimative*) *ranking function* on \mathbf{A} if and only if for all propositions A, B in \mathbf{A} : $\rho(W) = 0$, $\rho(\emptyset) = \infty$, $\rho(A \cup B) = \min\{\rho(A), \rho(B)\}$.

RBF Networks for Power System Topology Verification

Robert Lukomski

Wroclaw University of Technology, Poland

Kazimierz Wilkosz

Wroclaw University of Technology, Poland

INTRODUCTION

A necessary condition for monitoring and control of a Power System (PS) is possessing a credible model of this system. The PS model for a need of dispatchers in national control centre is created in real time. An important element of such a model is a topology model. PS Topology Verification (PSTV) is an important problem in PS engineering. Often this problem is solved together with PS state estimation (Lukomski, & Wilkosz, 2000; Mai, Lefebvre, & Xuan, 2003). Methods, that enable such a solution of the problem, are sophisticated and usually time consuming. They require successful state estimation performance but convergence problems may occur in the case of certain Topology Errors (TEs). Thus, a robust method for PSTV before a state estimation is desired.

BACKGROUND

Now, the growth rate of Artificial Neural Networks (ANNs) application in some PS subjects is observed (Haque, & Kashtiban, 2005). One of such a subject is PSTV. It can be considered as a pattern recognition problem and then also utilization of ANN technique for solution of PSTV can be taken into account (Alves da Silva, & Quintana, 1995; Souza, Leite da Silva, & Alves da Silva, 1996, 1997, 1998). There are many references in which PSTV with use of ANNs is described. In (Tian, Zhu & Zhang, 1995) use of ANN as a part of an expert system to rule extraction is presented. One of the first method for such PSTV has assumed utilization of one ANN for whole PS (Vinod Kumar, Srivastava, Shah, & Mathur, 1996). In the case of this method the complexity of the ANN structure grows rapidly with the size of a power network. There are the problems

with learning and classification process in a case of large ANNs. In other attempts to solve the problem of PSTV with use of ANNs one can observe utilization of additional knowledge on PS (Garcia-Lagos, Joya, Marin, & Sandoval, 2003; Delimar, Hebel, & Pavić, 2001, 2002, 2003a, 2003b). Such approach allows reducing size of utilized ANNs. The learning and classification process become more effective and the verification method is more efficient. The considered approach is also utilized in the case of the method, which is further presented.

DESCRIPTION OF THE CONSIDERED SOLUTION

To ensure that in the described method a larger knowledge on PS will be utilized than it is in other methods for PSTV, so-called unbalance indices are introduced. Taking into account the nature of the solved problem and to accomplish the best features of the PSTV, Radial Basis Function Networks (RBFNs) are utilized.

Power System Model

Elements of the PS topology model are nodes (representing electrical nodes) and branches (representing power lines, transformers, loads etc.). The assumption, that every branch in a PS model is modeled as the π -equivalent circuit (Fig. 1), is adopted. It is assumed that there is an accessible credible measurement data set of such quantities as: active and reactive power flows at the ends of each branch, power injections, loads and voltage magnitudes at each node. Usually, if a branch is not included in PS model the measurement data related to the branch are not taken into account in carried out analyses.

Figure 1. The assumed π model of the branch, $\mathbf{Z}_{kl} = R_{kl} + j X_{kl}$, $\mathbf{Y}_k = jB_{kl}$, $\mathbf{Y}_l = jB_{lk}$, $B_{kl} = B_{lk} = B$. B is a half of the capacitive susceptance of the branch.

Unbalance Indices

Using Kirchhoff's and Ohm's Laws, PS can be described by many relationships among measured quantities. If there are no TEs, all these relationships are fulfilled. When TE occurs some of the relationships become unfulfilled. It should be underlined that if a branch is not included in the PS model, the relationships for this branch are not considered, because measurement data for it are not taken into account. In the described approach to have possibility of examination of relationships for all nodes and all branches independently of their correct or incorrect inclusion in the PS model the so-called unbalance indices for nodes and branches are introduced (Lukomski, 2002). These indices are shown in Table 1.

It should be noted that the nodal unbalance indices instead of power flow measurement data are taken into account when branch unbalance indices are calculated. This fact allows considering branch unbalance indices independently of correct or incorrect inclusion of branches in the PS model.

Unbalance indices create characteristic sets of values for different cases of modeling PS. If the topology model is correct and there are no errors burdening measurement data, all nodal unbalance indices are equal to zero and branch unbalance indices are near to zero, as well. The same situation is, when there is a branch that is actually out of operation but it is included in the topology model (the inclusion error). If a branch is actually in operation in PS but it is not included in the topology model (the exclusion error), then; (i) the unbalance indices for terminal nodes of this branch considerably differ from zero, (ii) the unbalance indices for the considered branch are equal to zero, (iii) absolute values of the unbalance indices for other branches, that are incident to the nodes mentioned under (i), have especially large values.

It should be stressed that the behavior of unbalance indices for active power and for reactive power is the same for the same TE.

Analyzing unbalance indices for nodes and branches one can observe that the exclusion error of the branch j has no influence on: (i) unbalance indices for nodes, that are not terminal nodes of the branch j , (ii) unbalance indices for branches that are not incident to the

Table 1. Active and reactive power unbalance indices for nodes and branches

| | Node | Branch |
|---|------------------------------------|--|
| Active power | $W_{Pk} = \sum_{i \in I_k} P_{ki}$ | $W_{Pkl} = -W_{Pk} - W_{Pl} + R_{kl}W$ |
| Reactive power | $W_{Qk} = \sum_{i \in I_k} Q_{ki}$ | $W_{Qkl} = -W_{Qk} - W_{Ql} + X_{kl}W - B_{kl}(V_k^2 + V_l^2)$ |
| Description: W_{Pk} , W_{Qk} – unbalance indices for the node k for active and reactive power respectively; W_{Pkl} , W_{Qkl} – unbalance indices for the branch connecting the nodes k and l for active and reactive power respectively; I_k – a set of the nodes connected to the node k ; P_{ki} , Q_{ki} – active and reactive power flows in the branch connecting the nodes k and i at the node k ; R_{kl} , X_{kl} , B_{kl} – π model parameters for the branch connecting the nodes k and l (Fig. 1); V_k , V_l – voltage magnitudes at the nodes k and l respectively; $W = \frac{W_{Pk}^2 + (W_{Qk} + B_{kl}V_k^2)^2}{V_k^2}$ | | |

terminal nodes of the branch j . This observation shows existence of the local effect of TE. In this situation one can conclude about correctness of modeling the distinguished branch j on the basis of investigations of unbalance indices for certain areas of the power network: A_j^k, A_j^l , where: k, l are numbers of the terminal nodes of the branch j . $A_j^x \in \{k, l\}$ is the area, in which the branch j exists with the central node x . The area A_j^x comprises: (i) the node x (being one of the terminal nodes of the branch j), (ii) the branch j and all other branches incident to the node x , (iii) all nodes which are connected with the node x by the branches mentioned under (ii).

The Need of Use of ANNs

The earlier considerations regarding the unbalance indices pertain to the ideal situation. In real situations, measurement data are burdened with errors and also one can occur multiple TEs. In such situations, the earlier-described effects of TEs, effects of occurrence of measurement errors and TEs other than the one, that is incorrect modeling the considered branch, overlap each other. In real situations, the problem of PSTV is a complex problem (Lukomski, 2002). Taking into account the analysis of the behavior of the unbalance indices, one can state that in the described situation the problem of PSTV can be treated as the problem of pattern recognition and then utilization of ANNs can be considered as a proper idea of the solution of the PSTV problem.

On the basis of the earlier considerations it can be stated that the whole PSTV process can be decomposed into many simpler PSTV processes. One such process can be limited to the area A_j^x . If one assumes utilization of ANNs then for each of the distinguished processes the separate ANN should be constructed. Possibly simple and fast learning ANNs is desired and therefore attention has been paid to RBFNs (Meireles, Almeida, & Simões, 2003).

Principle of the Method

The proposed topology verification method consists of the following steps:

- calculation of unbalance indices for nodes and branches,

- pre-processing of the unbalance indices (pre-processing standardization),
- local classification,
- global classification.

The Pre-Processing Standardization

The pre-processing standardization of each unbalance index is realized using Radial Basis Function (RBF) unit with Gaussian transfer function:

$$f(w) = \exp\left(-\frac{w^2}{2\sigma^2}\right), \quad (1)$$

where: w is a value of the considered unbalance index, σ is the width parameter.

If an unbalance index is close to zero, the RBF unit output is close to one. If an unbalance index is significantly different from zero, the RBF unit output is close to zero. The pre-processing standardization allows keeping input values for local classifiers (in the next step of the method) in the range (0; 1]. The σ parameter for the index W_{pk} is calculated as follows (errors are assumed to be independent):

$$\sigma_{Wpk}^2 = a \sum_{l \in I_k} \sigma_{pkl}^2, \quad (2)$$

where σ_{pkl} is a standard deviation of data of the active power flow P_{kl} , a is a correction coefficient selected in an experimental way.

The width parameter for the branch unbalance index W_{pkl} is given by:

$$\sigma_{Wpkl}^2 = a (\sigma_{Wpk}^2 + \sigma_{Wpl}^2), \quad (3)$$

Width parameters for unbalance indices for reactive power are calculated in the similar way. One has assumed $a = 2$ for active power unbalance indices and $a = 1,8$ for reactive power unbalance indices.

The Local Classification

The purpose of the considered step of the method is classification of correctness of modeling branches of PS. During the described step the local effect of TEs is taken into account.

Each local classifier is RBFN. One local classifier corresponds to one node of a considered power network.

If the considered node has the number k then inputs for a local classifier, that corresponds to this node, are the results of the pre-processing of active and reactive power unbalance indices for: (i) the node k , (ii) the nodes having numbers from the set I_k , (iii) each branch connecting the node k and the node l , under assumption $l \in I_k$. The number of outputs of a local classifier is equal to the number of branches connecting the node k with the nodes having numbers from the set I_k . The criterion for taking a decision on correctness of modeling a branch is as follows:

$$D_l = \begin{cases} \text{the branch } l \text{ is incorrectly modelled} & \text{when } Y_l \leq -0.5 \\ \text{the neutral decision} & \text{when } Y_l \in (-0.5, 0.5) \\ \text{the branch } l \text{ is correctly modelled} & \text{when } Y_l \geq 0.5 \end{cases} \quad (4)$$

where: D_l is a decision, Y_l is an output value corresponding to the branch between the node k and the node l .

The Global Classification

The global decision unit processes decisions of the local classifications and produces final decisions on correctness of modeling branches of PS. To take a final decision on correctness of modeling a selected branch the outputs of two local classifiers are considered. These classifiers corresponding to the terminal

nodes of the considered branch. If decisions of local classifiers are different and none of them is the neutral decision or each of the local classifiers produces the neutral decision then the final decision is the neutral one. In other cases the final decision is different from the neutral one.

Computational Example

The presented method was implemented in the MATLAB environment. The method has been tested using the IEEE 14-bus test system (Fig. 2). It has been assumed that: (i) all branches are actually in operation, (ii) single and multiple TEs are considered, (iii) measurement data are burdened with small errors (Gaussian noise), (iv) wide range of load curve changes is taken into account.

Learning of each local classifier (being a RBFN) has been performed using Orthogonal Least Squares (OLS) algorithm (Chen, Cowan & Grant, 1991). Learning sets (200 – 400 learning patterns) were created separately for each RBFN. They comprised results of pre-processing unbalance indices and appropriate verification decisions. Learning of a RBFN was stopped when Sum Square Error (SSE) achieved the 10^{-4} level.

For the distinguished RBFN the number of hidden units depends on a number of branches incident to the appropriate node. For the particular nodes of the test system many different topologies of RBFNs were

Figure 2. The IEEE-14 bus test system

trained and tested. The characteristics of the local classifiers having the best performance is presented in Table 2.

Testing the local classifiers has been performed with use of the test set having about 2000 patterns that had not been used in the training phase. The cases with single and double TEs were considered. In the cases with single TEs only the correct decisions were produced. In the cases with double TEs the correct and neutral decisions were observed.

Table 3 shows a probability of taking the neutral decision p_n in the verification process for the different branches of the test system when there are double TEs. During the test stage, some doubtful cases have occurred and the neutral decisions have been taken for the branches with numbers 19 and 20. In these cases there has been no possibility to state the correctness of the considered branch in the test system. A reason was relatively small level of power flows in the mentioned branches. The obtained results show that the efficiency of the RBF classifiers is very high.

FUTURE TRENDS

Utilization of ANNs to handle the problem of PSTV seems to be very promising. However, the up-to-date methods do not give satisfying results in all possible real cases. The analyses have revealed that the application of pure neural models is not too effective. Utilization of ANNs and additional knowledge on PSs can result in much more efficient solutions. Also, it should be stressed that combining various artificial intelligence techniques can give interesting solutions from the view point of efficiency and performance time of a PSTV process.

CONCLUSION

The presented method allows performing PSTV independently of state estimation. It combines knowledge on PS and utilization of RBFNs. It utilizes the local effect of TEs. The whole PSTV process comprises many local processes realized by use of the classifiers assigned to the nodes of a power network. It makes possible to avoid constructing a large and complex ANN for a whole power network, as it is made in (Vinod Kumar, Srivastava, Shah, & Mathur, 1996).

Table 2. Characteristics of the local RBF classifiers corresponding to the nodes of the IEEE 14-bus test system. N – the number of the node, N_{inp} – the number of inputs, N_{hu} – the number of hidden units, N_{out} – number of outputs.

| | | | | | | | | | | | | | | |
|-----------|----|----|----|----|----|----|----|---|----|----|----|----|----|----|
| N | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 |

| N_{hu} | 20 | 51 | 30 | 98 | 76 | 47 | 38 | 4 | 62 | 18 | 15 | 20 | 25 | 23 |
| N_{out} | 2 | 4 | 2 | 5 | 4 | 4 | 3 | 2 | 4 | 2 | 2 | 2 | 3 | 2 |

Table 3. A probability of taking the neutral decision p_n in the verification process for the different branches of the test system when there are double topology errors.

| | | | |
|-------|--------|------|------|
| j | 1 - 18 | 19 | 20 |
| p_n | 0.00 | 0.11 | 0.10 |

Taking into account the decomposition of the PSTV process, the described method is close to the method from (Garcia-Lagos, Joya, Marin & Sandoval, 1998, 2003) and also to the method from (Delimar, Hebel & Pavić, 2001, 2002, 2003a, 2003b). However, the characterized method utilizes larger knowledge on PS than the method from (Garcia-Lagos, Joya, Marin & Sandoval, 2003) or the method from (Delimar, Hebel & Pavić, 2001, 2002, 2003a, 2003b). A consequence of this fact is decreasing sizes of ANNs of which utilization is assumed by the here-considered method in comparison with the method from (Garcia-Lagos, Joya, Marin & Sandoval, 2003) or the method from (Delimar, Hebel & Pavić, 2001, 2002, 2003a, 2003b).

The method assumes that the local classifiers are RBFNs. Their learning process is relatively short, comparing with multilayer feedforward neural networks. Using the OLS algorithm gives fast learning convergence. However, it should be stressed that RBFNs have much higher number of hidden units in comparison with multilayer feedforward neural networks.

The described method is capable to handle single and multiple TEs. It allows performing very efficient PSTV. Another advantage of the method is low sensitivity of the PSTV process quality to changes of PSs load curve.

KEY TERMS

Neutral Decision: In fact, the lack of any decision.

Orthogonal Least Squares (OLS) Algorithm: Algorithm describing a Gram-Schmidt orthogonalisation process which ensures that each new column added to the result matrix of the growing subset is orthogonal to all previous columns. This considerably simplifies the equation for the change in learning error and results in a more efficient algorithm.

Power System State Estimation: A process, which leads to calculation of a power system state vector us-

ing incoming measurement data and a mathematical power system model. A power system state vector fully specifies any state in which a power system can be.

Power System Topology Error: Inconsistency among the real power network connectivity and the power system topology model.

Power System Topology Model: A description of the physical connections in a power system.

Power System Topology Verification: Proving or disproving the correctness of a power system topology model.

Radial Basis Function Network: A type of artificial neural network which uses radial basis functions as activation functions. Typically, it consists of one hidden layer of Radial Basis Function (RBF) neurons (units). RBF hidden layer units have a receptive field which has a centre: that is, a particular input value at which they have a maximal output. Their output tails off as the input moves away from this point. Generally, the hidden unit function is a Gaussian. They are used in classification and approximation problems.

Unbalance Index: The left-hand side of the appropriate relationship, considered in the form in which its right-hand side is equal to zero. The mentioned relationship is a balance of active (reactive) powers at a node or a relationship among active (reactive) power flows at the ends of a branch.

Representing Non-Rigid Objects with Neural Networks

INTRODUCTION

Self-organising neural networks try to preserve the topology of an input space by means of their competitive learning. This capacity has been used, among others, for the representation of objects and their motion. In this work we use a kind of self-organising network, the Growing Neural Gas, to represent deformations in objects along a sequence of images. As a result of an adaptive process the objects are represented by a topology representing graph that constitutes an induced Delaunay triangulation of their shapes. These maps adapt the changes in the objects topology without reset the learning process.

BACKGROUND

Self-organising maps, by means of a competitive learning, make an adaptation of the reference vectors of the neurons, as well as, of the interconnection network

among them; obtaining a mapping that tries to preserve the topology of an input space. Besides, they are able of a continuous re-adaptation process even if new patterns are entered, with no need to reset the learning.

These capacities have been used for the representation of objects (Flórez, García, García & Hernández, 2001)] (Figure 1) and their motion (Flórez, García, García & Hernández, 2002) by means of the Growing Neural Gas (GNG) (Fritzke, 1995) that has a learning process more flexible than other self-organising models, like Kohonen maps (Kohonen, 2001).

These two applications, representation of objects and their motion, have in many cases temporal constraints, reason why it is interesting the acceleration of the learning process. In computer vision applications the condition of finalization for the GNG algorithm is commonly defined by the insertion of a predefined number of neurons. The election of this number can affect the quality of the adaptation, measured as the topology preservation of the input space (Martinetz & Schulten, 1994).

Figure 1. Representation of two-dimensional objects with a self-organising network

In this work GNG has been used to represent two-dimensional objects shape deformations in sequences of images, obtaining a topology representing graph that can be used for multiple tasks like representation, classification or tracking. When deformations in objects topology are small and gradual between consecutive frames in a sequence of images, we can use previous maps information to place the neurons without reset the learning process. Using this feature of GNG we achieve a high acceleration of the representation process.

One way of selecting points of interest in 2D shapes is to use a topographic mapping where a low dimensional map is fitted to the high dimensional manifold of the shape, whilst preserving the topographic structure of the data. A common way to achieve this is by using self-organising neural networks where input patterns are projected onto a network of neural units such that similar patterns are projected onto units adjacent in the network and vice versa. As a result of this mapping a representation of the input patterns is achieved that in post-processing stages allows one to exploit the similarity relations of the input patterns. Such models have been successfully used in applications such as speech processing (Kohonen, 2001), robotics (Ritter & Schulten, 1986), (Martinez, Ritter, & Schulten, 1990) and image processing (Nasrabati & Feng, 1988). However, most common approaches are not able to provide good neighborhood and topology preservation if the logical structure of the input pattern is not known a priori. In fact, the most common approaches specify in advance the number of neurons in the network and a graph that represents topological relationships between them, for example, a two-dimensional grid, and seek the best match to the given input pattern manifold. When this is not the case the networks fail to provide good topology preserving as for example in the case of Kohonen's algorithm.

REPRESENTATION AND TRACKING OF NON-RIGID OBJECTS WITH TOPOLOGY PRESERVING NEURAL NETWORKS

This section is organized as follows: first we provide a detailed description of the topology learning algorithm GNG. Next an explanation on how GNG can be applied to represent objects that change their shapes in a sequence of images is given. And finally a set of

experimental results using GNG to represent different input spaces is presented in.

The approach presented in this paper is based on self-organising networks trained using the Growing Neural Gas learning method (Fritzke, 1995), an incremental training algorithm. The links between the units in the network are established through competitive hebbian learning (Martinetz, 1994). As a result the algorithm can be used in cases where the topological structure of the input pattern is not known a priori and yields topology preserving maps of feature manifold (Martinetz & Schulten, 1994).

Recent studies has presented some modifications of the original GNG algorithm to improve the robustness of the cluster analysis (Cselényi, 2005), (Cheng & Zell, 2000), (Qin & Suganthan, 2004), (Toshihiko, Iwasaki & Sato, 2003), but none of them use the structure of the map as starting point to represent deformations in a sequence of objects shapes.

Growing Neural Gas

With Growing Neural Gas (GNG) (Fritzke, 1995) a growth process takes place from a minimal network size and new units are inserted successively using a particular type of vector quantisation (Kohonen, 2001). To determine where to insert new units, local error measures are gathered during the adaptation process and each new unit is inserted near the unit which has the highest accumulated error. At each adaptation step a connection between the winner and the second-nearest unit is created as dictated by the competitive hebbian learning algorithm. This is continued until an ending condition is fulfilled, as for example evaluation of the optimal network topology based on some measure. Also the ending condition could it be the insertion of a predefined number of neurons or a temporal constrain. In addition, in GNG networks learning parameters are constant in time, in contrast to other methods whose learning is based on decaying parameters.

In the remaining of this Section we describe the growing neural gas algorithm and ending condition as used in this work. The network is specified as:

A set N of nodes (neurons). Each neuron $c \in N$ has its associated reference vector $w_c \in R^d$. The reference vectors can be regarded as positions in the input space of their corresponding neurons.

A set of edges (connections) between pairs of neurons. These connections are not weighted and its purpose is to define the topological structure. An edge aging scheme is used to remove connections that are invalid due to the motion of the neuron during the adaptation process.

The GNG learning algorithm to approach the network to the input manifold is as follows:

1. Start with two neurons a and b at random positions w_a and w_b in R^d .
2. Generate a random input pattern ξ according to the data distribution $P(\xi)$ of each input pattern. In our case since the input space is 2D, the input pattern is the (x,y) coordinate of the points belonging to the object. Typically, for the training of the network we generate 1000 to 10000 input patterns depending on the complexity of the input space.
3. Find the nearest neuron (winner neuron) s_1 and the second nearest s_2 using squared Euclidean distance.
4. Increase the age of all the edges emanating from s_1 .
5. Add the squared distance between the input signal and the winner neuron to a counter error of s_1 such as:

$$\Delta error(s_1) = \|w_{s_1} - \xi\|^2 \quad (1)$$

Move the winner neuron s_1 and its topological neighbours (neurons connected to s_1) towards ξ by a learning step ϵ_w and ϵ_n , respectively, of the total distance:

$$\Delta w_{s_1} = \epsilon_w (\xi - w_{s_1}) \quad (2)$$

$$\Delta w_{s_n} = \epsilon_n (\xi - w_{s_n}) \quad (3)$$

If s_1 and s_2 are connected by an edge, set the age of this edge to 0. If it does not exist, create it.

6. Remove the edges larger than a_{max} . If this results in isolated neurons (without emanating edges), remove them as well.
7. Every certain number λ of input signals generated, insert a new neuron as follows:
 - Determine the neuron q with the maximum accumulated error.

- Insert a new neuron r between q and its further neighbour f :

$$w_r = 0.5(w_q + w_f) \quad (4)$$

Insert new edges connecting the neuron r with neurons q and f , removing the old edge between q and f .

- Decrease the error variables of neurons q and f multiplying them with a constant α . Initialize the error variable of r with the new value of the error variable of q and f .
8. Decrease all error variables by multiplying them with a constant β .
 9. If the stopping criterion is not yet achieved, go to step 2. (In our case the criterion is the number of neurons inserted)

Representation of 2D Objects with GNG

Given an image $I(x, y) \in \mathcal{R}$ we perform the transformation $y_{\mathcal{T}}(x, y) = \mathcal{T}(I(x, y))$ that associates to each one of the pixels its probability of belonging to the object, according to a property \mathcal{T} . For instance, in figure 2, this transformation is a threshold function.

If we consider $\xi = (x, y)$ and $\mathcal{P}(x) = y_{\mathcal{T}}(x)$, we can apply the learning algorithm of the GNG to the image I , so that the network adapts its topology to the object. This adaptive process is iterative, so the GNG represents the object during all the learning.

As a result of the GNG learning we obtain a graph, the Topology Preserving Graph $\mathcal{TPG} = \langle \mathcal{N}, \mathcal{C} \rangle$, with a vertex (neurons) set \mathcal{N} and an edge set \mathcal{C} that connect them (figure 1). This \mathcal{TPG} establishes a Delaunay triangulation induced by the object (O'Rourke, 2001).

Figure 2. Silhouette extraction

Representing Topology Deformations in Objects

The model is able also to characterize different parts of an object, or several present objects in the scene that had the same values for the visual property \mathcal{T} , without reset the different data structures for each one of the objects. This is due to the GNG capacity to divide itself into different parts when removing neurons and can be very useful to represent objects that change their topological structure breaking into small pieces or changing their shapes along a sequence of images. In this case a modification in the original algorithm of GNG must be done generating in step 2 a higher number of input signals to readapt from the previous map to the new image and avoiding steps 8 and 9 where neurons are deleted or added if necessary. None of the modifications of the original GNG algorithm to improve the robustness of the cluster analysis (Cselényi, 2005), (Cheng & Zell, 2000), (Qin & Suganthan, 2004), (Toshihiko, Iwasaki & Sato, 2003) use the structure of the map as a starting point to represent deformations in a sequence of objects shapes.

In this work GNG has been used to represent two-dimensional objects shape deformations in sequences of images, obtaining a topology representing graph.

When deformations in objects topology are small and gradual between consecutive frames in a sequence of images, we can use previous maps information to place the neurons without reset the learning process. Using this feature of GNG we achieve a high acceleration of the representation process.

For example in figure 3 are represented some objects with colour as a common feature in both images, that represent the same objects but as a foreground in white on the left and as a background in black on the right.

Experiments

To illustrate GNG capacities to represent topological deformations in objects, we have adapted the maps to an object shape that changes its topology from a compact square into four small squares in four steps (frames) obtaining graphs that represent the topology of the object shape along the images sequence but without reset the learning process for any image.

Figure 4 shows the original sequence of images used as input space for the self-organising map where from a homogenous square in the first image (on the left) four small squares are created in the last image (on the right). On the bottom of the figure are showed the results of the GNG adaptation establishing white

Figure 3. Representation of objects with similar visual properties as foreground and background

Figure 4. Results of GNG adaptation to changes in the input space

colour as a visual property of objects to be represented. From the first map (on the left), new maps are obtained based on the previous one without reset the learning process. This feature of GNG allows an acceleration of the images sequence representation.

As can be seen in the sequence of images, the map is able to separate the neurons into four groups representing the different squares in the original images when the distance between them is higher than the average of length of the edges that connects the neurons.

Figure 5 represents a sequence of deformations from a small circle to an ellipse and finally to a square used as input space to the GNG. The results of the adapta-

tion of the map without reset the learning algorithm between frames are showed.

The parameters used for the simulation are: $N=100$, $\lambda = 1000$ for the first map and 10000-20000 for the subsequent maps, $\epsilon_w = 0.1$, $\epsilon_n = 0.001$, $\alpha = 0.5$, $\beta = 0.95$, $\alpha_{\max} = 250$.

The computational cost to represent a sequence of deformations is very low, compared with methods based on the adaptation of a new map for any frame of the sequence, since our method does not reset the algorithm for new frames. This feature provides the method with real-time capabilities.

Figure 5. Object deformation with GNG adaptation

FUTURE TRENDS

The iterative and parallel performance of the presented representation model is the departure point for the development of high performance architectures that supply a characterization and tracking of non-rigid objects depending on the time available.

CONCLUSION

In this paper, we have demonstrated the GNG capacity of representation of bi-dimensional objects. Establishing a suitable transformation function, the model is able to adapt its topology to the shape of an object. Then, a simple, but very rich representation of the objects is obtained.

The model, by its own adaptation process, is able to divide itself so that it can characterize different fragments from an object or different objects in the same image. In addition, GNG can represent deformations in objects topology representing them along a sequence of images without reset the learning process. This feature accelerates the process of representation and tracking of objects.

KEY TERMS

Growing Neural Gas: A self-organizing neural model where the number of units is increased during the self-organization process using a competitive Hebbian learning for the topology generation.

Hebbian Learning: A time-dependent, local, highly interactive mechanism that increases synaptic efficacy as a function of pre- and post-synaptic activity.

Non-Rigid Objects: A class of objects that suffer deformations changing its appearance along the time.

Object Tracking: Is a task within the field of computer vision that consists on the extraction of the motion of an object from a sequence of images estimating its trajectory.

Self-Organising Neural Networks: A class of artificial neural networks that are able to self-organize themselves to recognize patterns automatically without previous training preserving neighbourhood relations.

Object Representation: Is the construction of a formal description of the object using features based on its shape, contour or specific region.

Topology Preserving Graph: Is a graph that represents and preserves the neighbourhood relations of an input space.

A Roadmap on Updates

INTRODUCTION

Updates, is a central issue in relational databases and knowledge databases. In the last years, it has been well studied in the **non-monotonic reasoning** paradigm. Several semantics for logic program updates have been proposed (Brewka, Dix, & Knonolige 1997), (De Schreye, Hermenegildo, & Pereira, 1999) (Katsumo & Mendelzon, 1991). However, recently a set of proposals has been characterized to propose mechanisms of updates based on logic and logic programming. All these mechanisms are built on semantics based on **structural properties** (Eiter, Fink, Sabattini & Thompits, 2000) (Leite, 2002) (Banti, Alferes & Brogi, 2003) (Zacarias, 2005). Furthermore, all these semantic ones coincide in considering the AGM proposal as the standard model in the update theory, for their wealth in properties. The AGM approach, introduced in (Alchourron, Gardenfors & Makinson, 1985) is the dominating paradigm in the area, but in the context of monotonic logic. All these proposals analyze and reinterpret the AGM postulates under the **Answer Set Programming** (ASP) such as (Eiter, Fink, Sabattini & Thompits, 2000). However, the majority of the adapted AGM and update postulates are violated by update programs, as shown in (De Schreye, Hermenegildo, & Pereira, 1999).

UPDATES

Update theory deals with knowledge base represented by a propositional theory. Besides, deals with incorporating new knowledge about a dynamic world. This dynamism is due to knowledge comes from the real

world, what means that knowledge evolves over time. This exchange rate mainly deals with changes in the extensional part of knowledge bases. However, the problem of updating the intensional part of a knowledge base (rules and descriptions of actions) remains basically unexplored. However, the problem of updates has attracted the researchers' attention in the last years who are dealing with such updates in the setting of logic programs. Though, some interesting proposals exist with foundation in Answer set programming (ASP), such as (Eiter, Fink, Sabattini & Thompits, 2000) (Leite, 2002) (Banti, Alferes & Brogi, 2003) (Osorio & Zacarias, 2003).

Answer set programming is a new paradigm used in the solution of the update issue. Particularly, this paradigm has taken bigger force around of update theory. A lot of theoretical work around updates under ASP has been developed by connoted researchers such as: Pereira, Alferes, Eiter, Osorio, Leite, Zacarias, and others. In the last years, a lot of theoretical work was devoted to explore the relationships between intuitionistic logic and ASP (Pearce, 1999) (Lifschitz, Pearce & Valverde, 2001). These results have recently provided a characterization of ASP by intuitionistic logic as follows: a literal is entailed by a program in the answer set semantics if and only if it belongs to every intuitionistically complete and consistent extension of the program formed by adding only negated literals (Pearce, 1999). The idea of these completions using in general intermediate logics is due to Pearce (Lifschitz, Pearce & Valverde, 2001). This logical approach provides the foundations to define the notion of non-monotonic inference of any propositional theory (using the standard connectives) in terms of a mono-

tonic logic (namely intuitionistic logic), see (Lifschitz, Pearce & Valverde, 2001) (Pearce, 1999).

STARTING WITH AGM

We start with an analysis on the AGM postulates and then we examine them with respect to update sequences. All these proposals are based on oneself principle of *causal rejection principle*. As is well known, if new knowledge of the world is somehow obtained, and it does not have conflicts with the previous knowledge then this new knowledge only expands knowledge. If by the contrary, new knowledge is inconsistent with the previous knowledge, and we want knowledge to be always consistent in all moment, we should solve this problem somehow. We point out that new information is incorporated into the current knowledge base subject to a *causal rejection principle*, which enforces that, in case of conflicts between rules, more recent rules are preferred and older rules are overridden.

An **update theory** is a knowledge base represented by a logic program. Then, let P be the program representing the current knowledge base, if it is updated by another program U , then P_U is a program updated of P if only if the models of P_U are the result of updating each of the models of P according to a given semantics S ; to each of these models apply the update request U to obtain a new set of models M ; P_U is any logic program whose models are exactly M .

The AGM approach proposes three basic operations on a belief set K : a) *expansion* $K + \Phi$, which is simply adding the new information $\Phi \in \mathcal{L}_B$ to K . b) *revision* $K * \Phi$, which is sensibly revising K in the light of Φ (in particular, when K contradicts Φ); and c) *contraction* $K - \Phi$, which is removing Φ from K .

On the other hand, AGM proposes a set of postulates, $K*1 - K*8$, that any **revision operator** $*$ mapping a belief set $K \subseteq \mathcal{L}_B$ and a sentence $\Phi \in \mathcal{L}_B$ into the revised belief set $K * \Phi$ should satisfy. We assume that K is represented by an epistemic state E , then the postulates $K*1 - K*8$ can be reformulated as in (Eiter, Fink, Sabattini & Thompits, 2000) as follows:

- (K1) $E * \Phi$ represents a belief set.
- (K2) $\Phi \in \text{Bel}(E * \Phi)$.
- (K3) $\text{Bel}(E * \Phi) \subseteq \text{Bel}(E + \Phi)$.
- (K4) $\neg\Phi \notin \text{Bel}(E)$ implies $\text{Bel}(E + \Phi) \subseteq \text{Bel}(E * \Phi)$.
- (K5) $\perp \in \text{Bel}(E * \Phi)$ only if Φ is unsatisfiable.

(K6) $\Phi_1 \equiv \Phi_2$ implies $\text{Bel}(E * \Phi_1) = \text{Bel}(E * \Phi_2)$.

(K7) $\text{Bel}(E * (\Phi \wedge \gamma)) \subseteq \text{Bel}((E * \Phi) + \gamma)$.

(K8) $\neg\gamma \notin \text{Bel}(E * \Phi)$ implies $\text{Bel}((E * \Phi) + \gamma) \subseteq \text{Bel}(E * (\Phi \wedge \gamma))$.

Katsuno and Mendelzon (1991) proposed a set of postulates where a change Φ to a belief base B are propositional sentences over a finitary language. Some of the outstanding differences between the postulates of the AGM and those of Katsuno and Mendelzon are that revision should yield the same result as expansion $E + \Phi$, providing Φ is compatible with E , which is not desirable for update in general. The postulate 8 says that if E can be decomposed into a disjunction of states (e.g., models), then each case can be updated separately and the overall result is formed by taking the disjunction of the emerging states.

Darwiche and Pearl (1997) have proposed postulates for iterated revision. This set of postulates is very simple and the majority of the adapted AGM and update postulates are violated by update programs. Another set of postulates for iterated revision, corresponding to a sequence E of observations, has been formulated by Lehmann (1995). Notice that in general the postulates proposed for iterated revision fail, and, with the exception of some postulates, each **change** is given by a single rule. Though, is that the two views described above amount to the same at a technical level.

All these approaches on the update issue consider it as a process of belief revision. However, following Gardenfors and Makinson (1991; 1994), **belief revision** can be related to non-monotonic reasoning by interpreting it as an abstract consequence relation on sentences, where the epistemic state is fixed. In the same way as Eiter we can interpret update programs as abstract consequence relation on logic programs. In spite of this, we should consider these proposals since for example Makinson (1993) considered a set of (desirable) **properties** for non-monotonic reasoning, and analyzed the behavior of some reasoning formalisms with respect to these properties.

Continuing with our research, immediately we comment in a general way the proposal of Alferes et al., (2000). They introduced the concept of dynamic logic programs as a generalization of both the idea of updating interpretations through revision programs and of updating programs as defined by Alferes and Pereira (1997) and by Leite and Pereira (1997). Syntactically, dynamic logic programs are based on generalized logic

programs (GLPs), which allow default negation in the head of rules, but no strong negation whatsoever (Eiter, Fink, Sabattini & Thompits, 2000). The way in that the models of a update sequence are defined by Alferes et. al., is similar to the transformation used by Eiter et. al. These are defined as the **stable models** of the program resulting from a syntactic rewriting. This is called a dynamic update. Elements of the sequence are generalized logic programs.

Alferes et. al. defined in (Alferes & Pererira, 2002) its semantics by means of a dynamic logic programming generated by the sequence of commands. Afterwards, a translation of these commands, (a LUPS program) to a generalized logic program where stable models exactly correspond to the semantics of the original LUPS program. In this proposal the authors considering that the knowledge evolves from one knowledge state to another. Thus, given the current knowledge state KS , its successor knowledge state $KS[U]$ is produced as a result of the occurrence of a non-empty set U of simultaneous updates. Each of the updates can be viewed as a set of actions and consecutive knowledge states are obtained as:

$$KS_n = KS_0[U_1][U_2] \dots [U_n]$$

where U_i 's represent consecutive sets of updates. This state is denote by:

$$KS_n = U_1 \oplus U_2 \oplus \dots \oplus U_n$$

Thus, in dynamic logic programming the models of a sequence of updates are defined as the **stable models** of the program resulting from a syntactic rewriting. In (Alferes & Pererira, 2002) it is demonstrated that revision programs and dynamic updates are equivalent, provided that the original knowledge is extensional, i.e., the initial program contains only rules of the form $A \leftarrow$ or $\text{not } A \leftarrow$.

One major difference can immediately be identified between our update programs and dynamic updates: In dynamic updates, the value of each atom is determined from the bottom level P_1 upwards towards P_n . the different evaluation strategy leads in effect to different semantics. Furthermore, Alferes et al. (2000) use a slightly non-standard concept of stable models. There is a semantic difference between dynamic updates and updates according to Eiter et.al (Eiter, Fink, Sabattini & Thompits, 2000).

On the other hand, one of the proposals more grateful on updates corresponds to (Eiter, Fink, Sabattini & Thompits, 2000). The authors in (Eiter, Fink, Sabattini & Thompits, 2000) redefine and implement an update process inspired in the proposal defined by Alferes et. al. you can refer to (Alferes & Pereira, 2002). The proposal (Eiter, Fink, Sabattini & Thompits, 2000) makes an exhaustive analysis of recent proposals based on non-monotonic logic. There, a syntactic redefinition of dynamic logic programs is presented, and semantically properties are investigated. In particular, a study on the dynamic logic programs verification of well known postulates of **belief revision** (Alchourron, Gardenfors & Makinson, 1985) is carried out. Also, structural properties of logic program updates are studied in (Eiter, Fink, Sabattini & Thompits, 2000). However, as happens in all works presented so far, most of the presented properties are not satisfied. This fact motivated our investigation to work towards a properties-based theory.

This is an approach to update non-monotonic knowledge bases represented as extended logic programs under the answer set semantics. They consider refinements of the semantics on the notion of minimality of **change**. This proposal proposes a mechanism for updates based on a sequence of logic programs. Informally, this program expresses layered derivability of a literal L , beginning from the top layer P_n and continuing downwards to the bottom layer P_1 . The rule r in layer P_i is only applicable if it is not refuted by a literal derived at a higher level that is compatible with $H(r)$. Inertia rules propagate a locally derived value for L downwards to the first level, where the local value is made global.

Continuing in this direction, we have been working in finding properties that our **update operator** satisfies (Osorio & Zacarías, 2003) (Zacarías & Osorio, 2005) (Zacarías, Osorio, & Arrazola, 2005). Our purpose is to build a semantics based on structural properties. This is our main objective in the update theory. In (De Schreye, Hermenegildo, & Pereira, 1999) (Osorio & Zacarias, 2003) (Zacarías, Osorio & Arrazola, 2005) (Zacarías, 2005) the authors present a set of properties that the update operator satisfies. In this paper we continue with this same research line presenting a novel proposal with the aim to enrich the update theory that we have begun in (Osorio & Zacarias, 2003) (Zacarías, Osorio & Arrazola, 2005) (Zacarías, 2005). This novel proposal contributes with two benefits. First, we conserve many

of the properties presented in previous works (Osorio & Zacarias, 2003) (Zacarias, Osorio & Arrazola, 2005) (Zacarias, 2005), such as: **Weak Irrelevance of Syntax** (WIS). This property is similar to one postulate proposed by AGM, but in this case for **nonmonotonic logic** and under **Answer Set Programming** (ASP) introduced and defined by (Gelfond & Lifschitz, 1988).

On the other hand, we conclude that many approaches about program updates do not satisfy many of the properties defined in the literature (Alchourron, Gardenfors & Makinson, 1985) (Eiter, Fink, Sabattini & Thompits, 2000) (Katsuno & Mendelzon, 1991) (Banti, Alferes & Brogi, 2003). This is partly explained by the non-monotonicity of logic programs and the causal rejection principle embodied in the semantics, which strongly depends on the syntax of rules. Furthermore, we consider that a good update theory is based fundamentally on a set of properties.

As result of a first analysis of a proposal presented in (Eiter, Fink, Sabattini & Thompits, 2000), we introduced in (Osorio & Zacarias, 2003), a new update operator. This proposal satisfies several properties of AGM postulates, among them, a new property called **Weak Irrelevance of Syntax**. These properties give to an agent an added value with respect to other proposals that do not satisfy them. It is necessary to highlight the simplicity of our proposal, which allows to an agent to be able to respond in a correct and opportune way.

Continuing our analysis on updates we present our main results about updates of logic programs: a properties-based approach published in (Zacarias, 2005). In this proposal we presented several properties on theory updates. We consider these properties from a non-monotonic reasoning perspective, by naturally interpreting program updates as non-monotonic consequence relations. In this proposal we consider our properties under N logic. Additionally, we have presented in (Zacarias, 2005) some examples about updates on answer set programming.

In (Zacarias, 2005) we have introduced a new proposal towards the enrichment of the update operator " \oplus ". There, we have presented a refinement of the stable model semantics for the update operator. Also, we presented a new property that allows us to face updates where new information contains rules that define a **conservative extension**. So, we gave an extension of our properties proven in (Osorio & Zacarias, 2003), under N logic. This approach is based on the work made by

Eiter et al. (Eiter, Fink, Sabattini & Thompits, 2000), and inspired in a recent approach presented by Alferes et al. (Banti, Alferes & Brogi, 2003). With this work, we improve and enrich the **update operator** proposed by Eiter et al. (Eiter, Fink, Sabattini & Thompits, 2000), giving as result a new update operator.

FUTURE TRENDS

Just as in (Eiter, Fink, Sabattini & Thompits, 2000) we coincide that because of apparent lack of minimality of change, we then considered refinements of the semantics in terms of minimal and strictly minimal answer sets. Several issues remain for further work. An interesting point (Eiter, Fink, Sabattini & Thompits, 2000) concerns the formulation of **postulates (principles or properties)** for update operator on logic programs and, more generally, on non-monotonic theories. As you can see in (Eiter, Fink, Sabattini & Thompits, 2000), several postulates from the area of logical **theory change** fail for update programs. This may be explained by the dominant role of syntax for update embodied by causal rejection of rules.

CONCLUSIONS

In this paper, we considered a new proposal to provide an **update process** to our agents. Our proposal is a novel and simple methodology that allows an agent to maintain updated its knowledge base in all moment. This provides an agent to behave in a rational way, similar to human behavior. Furthermore, it is an appropriate proposal for applications that require answers in real time. Also, this proposal opens the possibilities for building real-life applications, like intelligent agents whose rational component is modelled by a knowledge base, which is in turn maintained using update logic programs.

KEY TERMS

Beliefs: An agent whose knowledge base is the theory T believes F if and only if F belongs to every intuitionistically complete and consistent extension of T by adding only negated literals.

Causal Rejection Principle: Which enforces that, in case of conflicts between rules, more recent rules are preferred and older rules are overridden.

Equivalence: Two programs are *equivalent* if they have exactly the same answer sets.

Expansion: Which is simply adding the new information A to knowledge base KB .

Principle of Irrelevance of Syntax: The meaning of the knowledge that results from an update must be independent of the syntax of the original knowledge, as well as independent of the syntax of the update itself.

Update: Let P be the program representing the current knowledge base, if it is updated by another program U , then P_U is a program updated of P if only if the models of P_U are the result of updating each of the models of P according to a given semantics S ; to each of these models apply the update request U to obtain a new set of models M ; P_U is any logic program whose models are exactly M .

Weak Irrelevance of Syntax: $T_1 \equiv T_2$ implies $Bel(K \cup T_1) = Bel(K \cup T_2)$, where K , T_1 and T_2 are any theories, $Bel(T)$ defines the set of answer sets of T , \cup is the update operator, and understanding that equivalence means that both programs (T_1 and T_2) have the same answer sets.

A Robot Model of Dynamic Appraisal and Response¹

INTRODUCTION

A general goal of biologically inspired robotics is to learn lessons from actual biological systems and to find applications in robot design. Neural controllers and adaptive algorithms are major tools to model, at some level of abstraction, functions, structures, and behaviors present in biological systems. This involves, of course, identifying in virtue of what biological systems exhibit the behavioral characteristics we want to explore. One of the biological phenomena of great interest is *emotion*. Despite the effort of leading researchers to raise the question “whether machines can be intelligent without any emotions” (Minsky, 1988), AI interest in emotional phenomena has increased only in the last decade. An underlying assumption is that many cognitive functions, such as memory, attention, learning, decision making and planning, are at least partly based on emotional mechanisms in biological systems (Damasio, 1995).

One of the qualities of emotional behavior is its flexibility (Frijda, 1986), which contrasts with the rigidity of stereotyped behaviors such as reflexes or habits. Hence, it is relevant to investigate what it is that makes emotional behavior flexible. The body, through mostly chemical channels, produces diffuse effects on the neural system, processes at the root of emotional phenomena. Parisi has recently argued that in order “to understand the behavior of organisms more adequately we also need to reproduce in robots the inside of the body of organisms and to study the interactions of the robot’s control system with what is inside the body”

(Parisi, 2004), using the term *internal robotics* to denote the study of the interactions between the (neural) control system and the rest of the body.

Mechanisms that control homeostasis, based on hormonal modulation, can motivate appropriate behaviors (Avila-García & Cañamero, 2004; Gadanho & Hallam, 2001). Emergent behaviors from the interaction of a motivational system with the environment may be called emotional. Cañamero’s architecture, for example, consists of “a set of motivations; a repertoire of behaviors that can satisfy those internal needs or motivations as their execution carries a modification in the levels of specific variables; and a set of ‘basic’ emotions.” (Cañamero, 2005).

We consider emotional phenomena to emerge from a dynamic interaction between internal states, current perceptions and environmental relations, such that certain neural/physiological states have a close causal link with relational situations. This is, in a nutshell, the *embodied appraisal* hypothesis (Carlos Herrera, 2002; Prinz, 2004). We use two major concepts from the dynamical systems (DS) approach to cognition (Clark, 1997; Kelso, 1995): *collective variables* and *control parameters*. In (Carlos Herrera, 2002) we argue that internal states can be interpreted as collective variables of agent/ environment interaction that allow tracing concern-relevant situations. These variables are “non-specific: they do not prescribe or contain a code for the emerging structure” (Kelso, 1995). They also can be considered control parameters, as activation in the agent’s physiological substrate affects overall

action readiness (response, including perceptual and cognitive readiness).

BACKGROUND

An architecture for the design of emotional appraisal and response in artificial agents must take into account that emotions bear an intrinsic dynamic relationship between internal mechanisms, embodiment and situation (Frijda, 1993; Lazarus, 1991; Lewis, 2005). Emotions are emergent patterns that involve relational behavior as well physiological and psychological processes. In this section we argue that physiological states are essential for understanding emotion appraisal and response: they allow to trace agent-environment relations, and their modification is a mechanism for control of dynamics.

Appraisal is the process by which an agent is capable of recognizing that a situation is relevant to some of its concerns. From an information-processing perspective, an agent requires the capacity to differentiate situations which anticipate that a concern may be at stake if no proper response is carried out. Cognitive models consider appraisal the product of a reasoning engine (Zajonc, 1980), and robotic models often simplify this problem by manipulating the environment so that the concern-relevance of specific objects/stimuli is particularly salient (e.g. red color for dangerous objects).

Appraisal involves categorization, or hot cognition (Zajonc, 1980). The theory of embodied appraisal argues that the body plays an essential role in structuring sensory-motor patterns that, once processed by the brain, result in appraisal (Damasio, 2000). In the case of emotion certain physiological states are indicative of concern-relevant situations (Prinz, 2004). A high level of adrenaline, for instance, correlates with a wide class of emotional situations. The fact that the correlation is not one-to-one (physiological states are not sufficient to determine emotions) does not imply that they have no relationship to interactive relations. We understand embodied appraisal as dynamical coupling (attunement) in which some internal states are representative (collective variables) of agent/environmental interactions.

But emotion is not only about appraisal, but also response. Emotion theorists have proposed the notion of *action tendency* to explain the inherent relational purpose of emotional behavior: it establishes or modifies a relationship between the agent and the world “at

large” (Frijda, 1986). That means, “[a]ction tendencies are hypothesized ... for theoretical reasons: to account for latent readiness and to account for behavior flexibility” (Frijda, 1986). Tendencies imply a direction, although they are “not usually guided by a prior goal representation” (Frijda, 1986). It is also important to distinguish between action tendency and the function of emotional behavior. For example, the tendency in fear is withdrawal. The function, on the other hand, is protection. Similarly, the tendency in shock or surprise is interruption of ongoing activity, whilst the function is reorientation (Frijda, 1986). Withdrawal can come as, for example, freeze, flight, or faint; responses with very different functional roles. Hence, emotions are far from reflex-like responses. Even though emotion responses are often stereotyped and the product of evolution, we “should not conceive affect programs as fixed and peremptory” (Lazarus, 1991), i.e. “[t]o the extent that action programs are fixed and rigid, action tendency loses much of its meaning” (Frijda, 1986). On the contrary, emotional responses are dynamically situated, that is, outward behavior is configured in dynamic interaction with the environment.

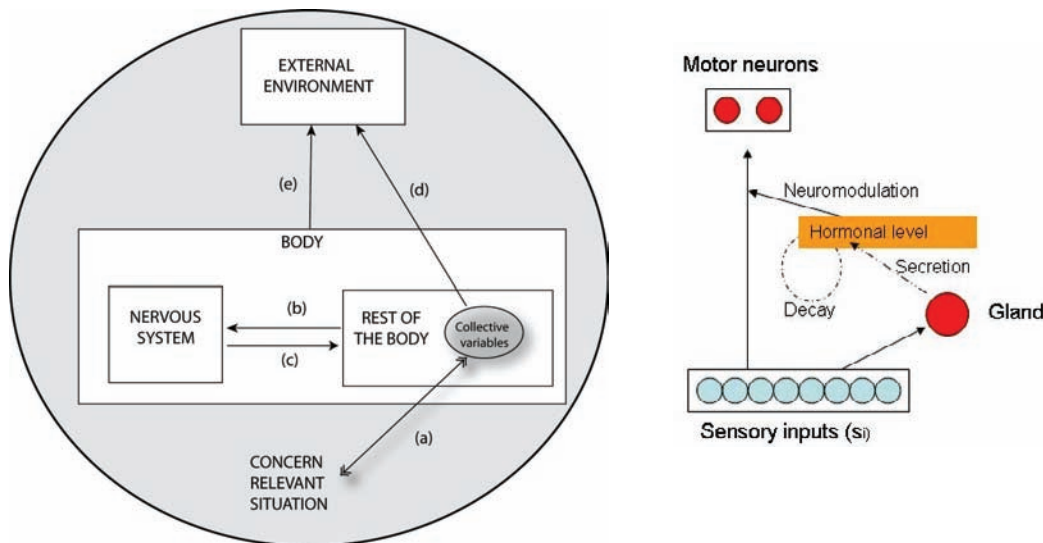

For modeling the mechanisms underlying action tendencies in biological agents, it should be noted how different physiological subsystems are dynamically interrelated. In particular, certain hormones (e.g. adrenaline), can affect, on the one hand, the autonomic system, whose activation involves a process of energy mobilization, and thus action readiness (Frijda, 1986). Hormones also act as neuromodulators, affecting the general processing of the nervous system, thus producing forms of cognitive or attention readiness.

MAIN FOCUS OF THE CHAPTER

This article presents a robotic approach for the emergence of a coupled agent-environment interaction with the ability to: (a) to appraise the concern-relevance of the situation, and (b) to control through activation of action readiness. The specific mechanisms that allow the emergence of such phenomena are based on sensitivity to overall patterns of interaction through the production of hormonal regulation.

The model illustrated in Figure 1 (Carlos. Herrera, 2006) is intended to illustrate the relationships between nervous system, body and world. The basic feature is that a number of internal variables in the body (such as

Figure 1. Left: Model of dynamic appraisal in embodied interaction. Relation between (a) physiological states and situations. (b,c) nervous system and rest of the body, (e, d) world and body. Right: Proposed controller for a Khepera robot (prey).

hormonal levels) allow the agent to trace the dynamics of some concern-relevant aspects of the relationship to the environment. Their processing can be conceived a simple form of body maps or feeling (Damasio, 1995, 2000).

This activation of internal states is integrated with current cognitive, perceptual and sensory-motor processes. The nervous system participates in the homeostatic balance, as hormonal production is a function of nervous activation – thus the collective variables are to some extent control variables: a change produces a change in action readiness, reflected in the dynamic relationship towards concern-relevant aspects of the situation. Sensory-motor activity (relationship of the nervous system to the environment), in conjunction with further nervous processing (secondary appraisal), produces a change in action tendency. Emotional behavior is the result of this process.

Experimental Setup

In this section we present a simple, preliminary experimental setup to the implementation of this model (Carlos. Herrera, 2006). We apply an evolutionary robotics approach evolving connection weights in

the neurocontrollers of simulated Khepera robots in a predator/prey scenario inspired by (Nolli & Floreano, 1998). Two robots, equipped with infrared sensors, are placed in random positions in a square environment surrounded by walls. The predator, which also has a camera, is rewarded for hitting the prey, which in turn is rewarded for avoiding the predator. Both robots are controlled by feedforward networks that map sensory inputs and to motor outputs/activations. To allow rich relational dynamics, the maximum speed of the prey is set to twice the predator's.

We abstractly model some of the functions of the endocrine system as a simple gland that secretes one type of hormone. The resulting hormonal level is intended to be a collective variable of the interaction, i.e. produce a function that allows us to trace concern-relevant situations. The model also requires that the hormone level has an effect on the generation of behavior through modulation of the neural controller. In order to achieve this, we feed it to the neural controller as an extra input. We have established the level of hormonal secretion as a function of the activity of the sensory cells and a fixed rate of hormonal absorption.

As mentioned above, the level of hormonal release is intended to be a collective variable of the interaction.

In order to achieve this, we paid attention to what situations are concern-relevant in the prey/predator scenario. We are interested in situations in which there is danger of being caught. Despite several possible strategies of approach and avoidance, given the speed of the prey, danger is most present when the prey is caught between predator and walls, whereas if no walls interfere, the prey can produce optimal escape behaviors. Extrapolating this observation, if a robot is near a wall and a predator, the sum of the activation of all sensors will be larger than when only one of them is present. Therefore it makes sense to establish a linear relationship between sensory activation and hormonal release, in line with intensity theories of emotion that relate emotion elicitation to “densities of neural firing” (Tomkins, 1962) (we do not claim intensity theories to be complete, though). We therefore define hormonal release as the sum of the activation of all other sensors. The decay function of the hormone level, or rate of absorption, is set to 2, i.e. at every time step, the hormone level will be divided by 2. The resulting level is fed back in to the neural controller as an extra input, playing the role of a parametric bias with a neuromodulatory effect on the motor output. The hormonal level can thus be expressed as a function of current level and sensory states as follows:

$$E_t = \left(E_{t-1} + \sum_{i=1..8} S_i \right) / 2$$

The controller weights of the controller and the modulation effect of the hormonal level are evolved,

while the production and absorption of hormones is kept fixed. If, as assumed, the level of hormone is significant of a class of situations (danger), then the robot can be expected to use it for the evolution of adaptive emotional behavior.

Results

As with other experiments in co-evolution, performance of prey and predator along the evolutionary process are co-dependent, and cycles can be observed. It is nevertheless possible to analyze cross generational strategies and fitness (Nolfi & Floreano, 1998). Due to limited space, we will here only analyze the behavior of a single generation (100). In this analysis we will verify whether: (a) the hormonal level can be considered a collective variable of the dynamics of interaction, that is, it allows us to track situations in which the prey is between wall and predator, (b) the hormonal level acts as a parametric bias for the neural controller so as to generate an action tendency that changes the relationship to the environment (whose function is to safeguard the prey’s concern, i.e. to escape), and (c) the resulting behavior shows a degree of flexibility measured as robustness in unforeseen circumstances.

Figure 2 shows the prey’s behavior and its relationship to the hormone level. A high hormonal level modulates the normal behavior (circular), producing a straightforward fast motion (right). This change in behavior is correlated to dangerous situations (caught between predator and wall). The prey thus is capable of appraising concern-relevant situations, by means of attunement through an appropriate collective variable

Figure 2. Left: Interaction between predator (black, discontinuous trace) and prey. At the marked points (1, 2, 3, 4) the prey was caught between wall and predator. Center: level of hormonal activation throughout the interaction. Right: close up of an escape behavior.

Table 1. Performance in original and modified environments

| | No Obstacles | One Obstacle | Two obstacles |
|----------------|--------------|--------------|---------------|
| Prey escapes | 56% | 40% | 33% |
| Predator kills | 39% | 39% | 36% |
| Prey crashes | 5% | 21% | 31% |

represented by a simulated physiological function. Further analysis of this behavior and control dynamics can be found in (Carlos Herrera, Ziemke, & Moffat, 2006).

In terms of flexibility our hypothesis was that, in any scenario in which the concern-relevance of the robot is represented by such a variable, the prey's ability for escape should not be seriously reduced. We tested the performance of prey and predator with one and two obstacles placed in random positions, for 1000 runs (note that the original evolutionary process was carried out without obstacles). Given that the evolved predator cannot determine whether a prey is hiding behind an obstacle, we exclude the runs in which the predator crashed without entering the prey's sensor range.

As the table shows, environmental changes do affect the prey's ability to escape. The presence of obstacles has a limited effect on the functionality of the prey's behavioral strategy for escaping the predator, although the proportion of times where the prey crashes increases significantly. Comparing the flexibility with that of evolved reactive controllers, we found that the rate of successful escapes decreases more rapidly in favor of predator catches, while crashes remain stable (Carlos. Herrera, 2006). We could draw a parallel from such results to real emotional behavior: if we react emotionally to dangerous situations, we will be more likely to escape, but also more likely to harm ourselves. Being involved in a fast fleeing behavior implies that the danger of bumping into further danger increases. This is congruent with emotion theory "not all behavior elicited by emotional events can be considered coping activity ... Instrumental behavior, too, shows dysfunctional or non-functional features, among them sheer disturbance manifestations like decreased precision of skilled movements" (Frijda, 1986).

FUTURE TRENDS

Despite increasing interest in the modeling of emotions in robotics, it remains one of the cornerstones of Artificial Intelligence. In this article, we have presented a dynamical-embodied approach. Some of the obvious limitations of this initial experimental setup should be avoided in further work. For instance, it would be interesting to let the control of the 'endocrine gland', as well as the modulation of behavior co-evolve or co-develop, and to investigate the role evolution and learning may play in emotional attunement. This would involve research into the capacities of neural networks to learn temporal patterns of concern-relevance. We have here also considered the physiological system only in its relationship to the nervous system, and not in its relation to body dynamics, leaving aside the autonomic system and its energy mobilization role. This allowed us to functionally replace the physiological system by a one-dimensional hormone level. More complex robotic physiologies, exploring relationships between body states and their relationship to sensors, motors, and nervous system should be investigated.

There are two short term experimental goals for further work. First, given that it is not always possible for the designer to identify concern-relevant situations and possible ways to trace them through internal mechanisms, and in search of increased robotic autonomy, we plan to find self-organizing techniques to achieve similar results. In particular, we are considering the use of evolution and learning, as well as novel mechanisms such as anticipatory networks and liquid state machines, to allow an internal structure to identify and gain sensitivity to such situations. A more realistic model of the physiological systems involved is also necessary, as arguably the control architecture presented here is 'just' a form of recurrent neural network. Finally, we will explore the role of a hormonal regulation system

within a framework of behavioral attractors, in order to be able to carry out detail dynamical system analysis of parametric/behavioral biases and the resulting action tendencies.

CONCLUSION

In this paper we suggest a biologically inspired approach to flexible behavior through emotion modeling. We consider emotion to emerge from relational interaction of body, nervous system and world, through sensory-motor attunement of internal parameters to concern-relevant relationships. We interpret such relationships with the notions of collective variable and control parameters.

The preliminary experiments presented here indicate the viability of the model and the potential benefits for robotic behavioral flexibility. If interaction between an agent and the environment can be conceived as a dynamical system with certain collective variables, it is worthwhile considering the possibility for the agent to embody emotional mechanisms that allow the agent to trace such collective variables.

The approach presented involves an alternative way of considering the problem of adaptation and cognition from a dynamical system perspective.

- Collective variables and control parameters are considered useful for the construction of adaptive dynamical systems.
- Perception is not directed exclusively to objective features of the environment, but first and foremost to establishing agent/environment relationships and the attunement of action tendencies.
- Third, neural/computational processing is not the only mechanism for extracting such global characteristics, but physiological aspects of embodiment, e.g. hormonal modulation, can carry out essential information-processing functions too.

In summary, this approach suggests that instead of considering sensory stimuli as the primary basis for perception, proprioceptive feedback plays a constitutive role in gaining appropriate information about agent/environment relations, and thus the environment itself. This approach can enlighten the notion of hot cogni-

tion and its relation to standard cognitive/perceptual mechanisms and representational content.

KEY TERMS

Action Readiness / Tendencies: Physiological states affect the readiness for engagement in certain dynamics of the interaction

Artificial Emotion: The attempt to synthesize in robots or artificial systems some of the functional properties of emotion.

Embodied Appraisal: Theory that asserts sensitivity to concern-relevant situations is facilitated by physiological and homeostatic mechanisms in an embodied agent.

Emotions: Phenomena present in biological systems by which an adaptive agent is capable of appraising the concern-relevance of situations and provide flexible responses through generation of physiological, cognitive and behavioral readiness.

Collective Variable / Control Parameter: In dynamical systems theory, collective variables allow tracing global dynamic patterns, control parameters lead the system through such patterns.

Concerns: The conditions under which a system can continue to function.

Hormonal Modulation: Change in the functionality of neural, sensory and motor systems achieved through changes in hormonal levels.

Neuro-Robotics: Approach to robot control through the use of neural networks.

ENDNOTE

¹ This paper represents a revised version of the paper "Behavioral flexibility: An emotion based approach", presented at the IWANN'07 conference. This work has been partly supported by a European Commission grant to the project "Integrating Cognition, Emotion and Autonomy" (IST-027819,) as part of the European *Cognitive Systems* initiative.

Robots in Education

Muhammad Ali Yousuf

Tecnologico de Monterrey – Santa Fe Campus, Mexico

INTRODUCTION

The new paradigm in engineering education demands hands-on training of the students using technology oriented projects. The roots of this approach can be traced back to the work of **Seymour Papert** in 1970s when he built a programmable turtle with a reflective light sensor (Papert, 1971). His ideas ultimately lead to the educational theory of **constructionism** (Papert, 1986 and Harel & Papert, 1991). According to this theory, students learn very effectively when they are involved in the creation of an external object that lives in the real world. Learners use this object to think with, and to relate ideas of, their subject of inquiry (Bourgoin, 1990). From an educational point of view, the theory of Papert can be linked to the **constructivist** theory of Jean Piaget (Paiget, 1972). According to this theory, learning comes from an active process of knowledge construction. This knowledge can be gained through real life experiences and linked to a learners' previous knowledge. The concept of turtle was evolved further at MIT and became the famous **Programmable Brick** by **Fred Martin** who also developed new learning environments and methodologies based on this concept (Martin, 1988 and Martin 1994). The unusual idea put forward by the Brick, at least at the time of its invention, was the incorporation of the "design" work into the learning process. Students were not only users in this case, but were actively involved in the design process, while solving their problems (Martin, 1996a). The 'Brick' was later adopted and incorporated by the LEGO MINDSTORMS kit (RCX in 1998 and NXT made available in 2006). The use of the name "MINDSTORMS" can also be traced back to the book by Seymour Papert (Papert 1980). Versions of these Bricks for economically challenged communities have also been proposed recently (Sipitakiat, et al, 2004).

The **active learning** methodology (Harmin and Toth, 2006) uses this philosophy of involving students in their own learning through class discussions and group problem solving and proves to be effective at least in certain cases. Robots have become a major

player in this area and have been employed in improving the quality and level of student learning, ranging from primary schools to graduate level. As pointed out by Resnick and Martin (Resnick and Martin, 1990), "Creatures built from Electronic Bricks fall on the fuzzy boundary between animals and machines, forcing students to come to terms with how machines can be like animals, and vice versa". In engineering courses incorporating connectionism approach, the students are asked to design and program a robot for a specific task. They also work in small teams and help and learn from each other.

However it is important to know what is currently available to an educator so that he/she can develop the required skills, abilities, attitudes and values in students. In this article we identify some of the major research centres working in the area of education utilizing robots and discuss some of the robotic kits now available to educators. We also comment on the famous robotic competitions worldwide.

BACKGROUND

Many researches have tried to include a project-oriented approach to the teaching of engineering subjects. This approach has the benefit of allowing students to seek information on their own while developing a well defined product. The use of robots in enhancing the quality of education at a university level has been discussed by many authors (Takahashi et al, 2006, Gage & Murphy 2003, Matsushita et al 2006). Students from school to undergraduate level have been involved in microcontroller based robotic projects. They can design, build and test their robots themselves and that helps them later in their education. Mukai and McGregor (Mukai and McGregor, 2004) have gone to the level of teaching control to eight graders in public schools.

Robots can help educators in teaching and learners in learning various branches of basic sciences. This is in addition to their obvious use in engineering courses. Mathematics (Algebra, geometry, matrices, calculus),

Physics (electricity, force, Newton's laws, momentum, rotations and angular momentum) are few examples (Yousuf et al., 2006). Their connection to biology comes through understanding and linking of human sensors to robotic or electronic sensors. Bratzel (Bratzel, 2005) uses engineering principles to teach physics and physical science by incorporating LEGO robots. She introduces, in chapters of increasing difficulty, concepts of motion, forces, fluids, stability, work and energy, etc. Bratzel has also correlated the activities in her book with the national science content (in USA) standards for grades 5-12, and hence makes for a good choice for educators at that level.

The purpose of integrating robotics is not just to create excitement among students but to use this excitement to help them in learning what they find difficult to learn using conventional methods. All the educators want to develop certain abilities, values and attitudes among their students. Some of the international accrediting organizations, like the Accreditation Board for Engineering and Technology recommend the use of a “**competency-based learning**” methodology for course development (Earnest, 2005 and Criteria for Accrediting Engineering Programs, 2006). The core of this system is that all activity (in the classroom, laboratory or projects) must be focused on pre stated competencies by using structured learning objectives. This system also demands the evaluation to be based on the competencies developed by the students. This can only be done by looking at concrete evidence (e.g., electrical or mechanical systems developed, software, technical reports, etc). Once again, the use of robots provides the educator with well defined competencies to be evaluated precisely.

EDUCATIONAL ROBOTS

We divide this part into subsections discussing various aspects of the main theme. Since each of these subjects is sufficiently broad in itself, we concentrate on a few representative cases only.

Research Groups in the Area of Educational Robotics

This is an area of immense activity and the number of research groups active in this area is extremely large. Almost all the robotic research groups have an interest

in the educational aspects of the subject. Many have tried to involve their own undergraduate students into the process and have gained new and deeper insights into student behaviour and learning.

Massachusetts Institute of Technology

MIT has been active in the area of robotics for a long time but it was in 1989 that Fred Martin (Martin 2001) started a worldwide movement in educational robotics by introducing his now famous undergraduate design contest. This was also the launching of the corresponding robot “brain” called the Handyboard (Handyboard). It is now being used by educators worldwide together with the Interactive C language to program the system (Butler et. al., 2006). This system is powerful enough to have industrial applications. The work of Fred Martin was continued later with Mitchel Resnick's Life-Long Kindergarten group (Kindergarten Group). This work was partly sponsored by the LEGO Group and became the foundation for the LEGO MINDSTORMS Robotics Invention System (to be discussed later).

NASA Robotics Alliance Project

The Robotics Alliance Project is an initiative of the **NASA**, the National Aeronautics and Space Administration in USA. It is based on the idea that NASA is going to need many more robot engineers for its space endeavours in the future and the only way to have quality engineers in the future is to invest in their training (RAP). Hence the project starts at the level of K-12 and does it through a variety of robotics programs, competitions and curriculum development. Their web site offers links to curriculum resources starting from primary to doctoral level. It also lists some of the major robotic competitions, and internship opportunities for students, etc. NASA also provides video and webcast archives for educators.

Carnegie-Mellon University

The robotics institute at the **Carnegie-Mellon University** is one of the largest of its type and has various projects with an educational impact. The CREATE project, which is an acronym for Community Robotics, Education and Technology Empowerment (CREATE) has research programs in curriculum design for teaching robot programming at the secondary school level and

beyond. They are also developing curriculum that will help middle and high school educators. Another valuable contribution by the same group is the development of a fully accredited robotic exploration course for high school juniors. The course is offered in summer and allows students to build robots using special fast-build kits. These kits have also been designed at CMU and include even a vision system allowing students to develop rover missions in the classroom and home environments (Nourbakhsh et al., 2005). Students then go home together with the robot. This way student can keep working on the subject after leaving the center.

Fraunhofer Institut Intelligente Analyse und Informationssysteme

The **Fraunhofer AIS** in Germany (Fraunhofer), sponsored by the Federal Ministry of Education and Research, is active in the educational aspects of robotics. They have developed a robot called Roberta, which conveys the knowledge about engineering and computer science to youngsters in an exciting way. Their particular focus is female population. Dozens of tutors have been guided in the use of this methodology and a few hundred students (more than three-fourth girls) have been trained. Tutors get training at the Fraunhofer AIS with specially developed teaching material to support learning. A national network of regional Roberta centers is being established to support tutors locally, to ensure nation-wide exchange of experience, and to disseminate the results of this project.

Educational Robot Kits

Educational robotic kits provide the users everything needed to build and program a robot. Some of them are more flexible than others, but each comes with its own programming language or programming environment. We discuss here some of them.

LEGO MINDSTORMS RCX and NXT Robots

As mentioned in the introduction above, it was an idea developed at MIT and introduced to the mass market by the LEGO Group (LEGO) in 1998. The **LEGO MINDSTORMS** robots are perhaps the simplest kits to start with, yet they are general and broad enough to be used as pedagogic platforms for training even at the

university level. Banking upon the students' familiarity with LEGO (those who are not familiar need very little extra time to start with), and utilizing a specially developed, highly visual programming language, the system helps kids from six years upward to learn and enjoy robotics. The system comes complete with online tutorials and is backed by innumerable web sites, books and tutorials. The newer version is called MINDSTORMS NXT and is even more flexible and powerful with some new sensors added and some of the older sensors upgraded. The new servo motors have been fitted with rotation sensors, allowing precise position control.

Parallax Systems

Parallax, Inc., (Parallax) is a developer of electronic systems (including robots) generally for higher level students though they do have systems for ages eight and above. Scribbler™ Robot for example, is meant for first-time programmers and roboticists age eight and up. The more advanced systems designed for experienced users include the Toddler® Robot, QuadCrawler and HexCrawler robots. The big advantage for educators is the large number of books, manuals and curriculum material available for these systems. Most of it is available free from the company web site and / or included in the kits.

Fischertechnik Reconfigurable Robot Kits

The **Fischertechnik** systems (Fischerwerke Artur Fischer GmbH) developed in Germany, are some of the most advanced robotic invention systems available. These systems allow students of all ages (even adults) to enjoy the field with flexible robotic kits. They also provide curriculum material for those willing to incorporate Fischertechnik into their classes. These systems are easy to program and come with a variety of sensors, motors, LEDs, etc. The kits can be used to teach advanced concepts in engineering too, including PLCs or Programmable Logic Control.

Robotic Competitions

Robotic competitions are an ideal way to keep the interest of the students alive and to give them a well-defined target to achieve. Most of the competitions also give very strict guidelines as to what can be used in

the construction of the system and who can participate. Many of the international competitions discourage teacher participation in the final presentation and hence allow students to grow and develop into self responsible persons. These competitions also grade students based on their group work, cleanliness, and presentation skills. In a nutshell, they are an excellent way of “standardizing” curriculum and assessment.

According to the Manchester based organization, “For Inspiration and Recognition of Science and Technology (**FIRST**), the FIRST Robotics Competition involves around 32,500 students in 2007. The junior version, called the FIRST LEGO League has been designed for children in age group 9-14 years. An estimated number of 88,000 children participated in this activity in 2006. There are dozens of other local robotic competitions all over the world for which there is no statistics available. However a search on any of the Internet search engines brings a large number of pages (e.g. the Robot Competition FAQ). Many of these are confined to a university, college or school. But in many cases the models can be followed and replicated at other places. The famous 6.270 Autonomous Robot Design Competition at MIT (MIT 6.270) is a good example and has been running successfully for more than two decades. Most of the research groups mentioned above may also be contacted as they frequently arrange national level competitions.

FUTURE TRENDS

The field of educational robots is full of promising directions. One important factor is the development of generic robot systems and the standardization of corresponding robot control software. **Microsoft Robotics Studio** (Microsoft Robotics Studio) is one of the most recent efforts in the direction of software standardization. It allows ANY robot to be controlled through a single platform. Companies like Parallax have already developed free examples for users to try on their boe-bot. On the hardware side also we are going to see more modular systems with flexibility and extensibility. The **MIT Tower** (Lyon, 2003) is a typical product of this type. Though not yet commercially available, it allows the user to start with a basic system and then to go on adding functionality depending upon requirements. Currently available modules are for sensing, actuation, data storage, and infrared communication. They

plan to add new ones for enhanced display output and high-speed wireless communication, etc.

CONCLUSION

In this article we have made an attempt to provide a brief overview of the state of the art in educational robotics, the work of major research groups and the offerings of commercial vendors for educators. Comments on the future directions in educational robotics have been made. Most of the efforts in this direction have started to take advantage of the experiences of others and we hope to see more balanced and well thought-out curricula to be developed for each of the major areas of basic sciences.

KEY TERMS

Active Learning: The methodology which demands students to participate actively in their own learning, guided and supervised by the educator.

Competency Based Learning: A system of learning which represents a dynamic mixture of knowledge, understanding, capacity and ability. The competencies are measurable outcomes of learning and hence can be evaluated at the end of the process.

Constructionsim: According to the constructionist learning theory, people learn most effectively when they are involved in the creation of an external artefact in the world. This artefact becomes an “object to think with,” which is used by the learner to explore and embody ideas related to the topic of inquiry (Martin, 1996b).

Constructivism: An educational theory or school of learning, based on the idea that knowledge is constructed by the learner based on mental activity. Learners create a mental image of how the world operates and they adapt and transform their understanding using their earlier knowledge.

Industrial Robotic Manipulators: Mechanical arms used in industry, with sensor feedback and automatic control software.

Mobile Robots: Robots with the capability to move autonomously from one place to the other, including wheeled, legged, submerged and flying robots, etc.

Pedagogy: The art (or science) of being a teacher but commonly referred to as the technique used in instruction.

Robust Learning Algorithm with LTS Error Function

Andrzej Rusiecki

Wroclaw University of Technology, Poland

INTRODUCTION

Feedforward neural networks (FFNs) are often considered as universal tools and find their applications in areas such as function approximation, pattern recognition, or signal and image processing. One of the main advantages of using FFNs is that they usually do not require, in the learning process, exact mathematical knowledge about input-output dependencies. In other words, they may be regarded as model-free approximators (Hornik, 1989). They learn by minimizing some kind of an error function to fit training data as close as possible. Such learning scheme doesn't take into account a quality of the training data, so its performance depends strongly on the fact whether the assumption, that the data are reliable and trustable, is hold. This is why when the data are corrupted by the large noise, or when outliers and gross errors appear, the network builds a model that can be very inaccurate.

In most real-world cases the assumption that errors are normal and iid, simply doesn't hold. The data obtained from the environment are very often affected by noise of unknown form or outliers, suspected to be gross errors. The quantity of outliers in routine data ranges from 1 to 10% (Hampel, 1986). They usually appear in data sets during obtaining the information and pre-processing them when, for instance, measurement errors, long-tailed noise, or results of human mistakes may occur.

Intuitively we can define an outlier as an observation that significantly deviates from the bulk of data. Nevertheless, this definition doesn't help in classifying an outlier as a gross error or a meaningful and important observation. To deal with the problem of outliers a separate branch of statistics, called robust statistics (Hampel, 1986, Huber, 1981), was developed. Robust statistical methods are designed to act well when the true underlying model deviates from the assumed parametric model. Ideally, they should be efficient and reliable for the observations that are very close to the

assumed model and simultaneously for the observations containing larger deviations and outliers.

The other way is to detect and remove outliers before the beginning of the model building process. Such methods are more universal but they do not take into account the specific type of modeling philosophy (e.g. modeling by the FFNs). In this article we propose new robust FFNs learning algorithm based on the least trimmed squares estimator.

BACKGROUND

The most popular FFNs learning scheme makes use of the backpropagation (BP) strategy and a minimization of the mean squared error (mse). Until now, a couple various robust BP learning algorithms have been proposed. Generally, they take advantage of the idea of robust estimators. This approach was adopted to the neural networks learning algorithms by replacing the mse with a loss error function of such a shape that the impact of outliers may be, in certain conditions, reduced or even removed.

Chen and Jain (1994) proposed the Hampel's hyperbolic tangent as a new error criterion, with the scale estimator β that defines the interval supposed to contain only clean data, depending on the assumed quantity of outliers or current errors values. This idea was combined with the annealing concept by Chunag and Su (2000). They applied the annealing scheme to decrease the value of β , whereas Liano (1996) introduced the logistic error function derived from the assumption of the errors generated with the Cauchy distribution. In a recent work Pernia-Espinoza et al. (2005) presented an error function based on tau-estimates. An approach based on the adaptive learning rate was also proposed (Rusiecki, 2006). Such modifications may significantly improve the network performance for corrupted training sets. However, even these approaches suffer from several difficulties and cannot be considered as universal (also

because of properties of applied estimators). Besides, very few of them have been proposed until today and they exploit the same basic idea, so we still need to look for new solutions.

ROBUST LTS LEARNING ALGORITHM

Least Trimmed Squares

The least trimmed squares estimator (LTS), introduced by Rousseeuw (1984, 1985) is a classical high breakdown point robust estimator, similar to the slower converging least median of squares (LMS) (Rousseeuw, 1984). The estimator and its evaluations are often used in linear and nonlinear regression problems, in sensitivity analysis, small-sample corrections, or in simple detecting outliers. The main difference between the LTS estimator and the least sum of squares, but also M-estimators, is obviously the operation performed on residuals. In this case however, robustness is achieved not by replacing the square by another function but by superseding the summation sign with something else. The nonlinear least trimmed squares estimator is then defined as:

$$\hat{\theta} = \arg \min_{\theta \in R^p} \sum_{i=1}^h (r_i^2) \quad (1)$$

where $(r_i^2)_{1:n} \leq \dots \leq (r_i^2)_{n:n}$ are the ordered squared residuals $r_i^2(\theta) = \{y_i - \eta(x_i, \theta)\}^2$, y_i represents the dependent variable, $x_i = (x_{i1}, \dots, x_{ip})^T$ the independent input vector, and $\theta \in R^p$ denotes the underlying parameter vector for the general nonlinear regression model. The trimming constant h must be chosen as $n/2 < h \leq n$ to provide that $n-h$ observations with the largest residuals do not directly affect the estimator. Under certain assumptions the estimator should be robust not only to outliers (Stromberg, 1992) but also to the leverage points (grossly aberrant values of x_i) (Rousseeuw, 1987).

Derivation of the LTS Algorithm

For simplicity, let us consider a simple three layer feedforward neural network with one hidden layer. The net is trained on a set of n training pairs:

$$\{(x_1, t_1), (x_2, t_2), \dots, (x_n, t_n)\},$$

where $x_i \in R^p$ and $t_i \in R^q$. For the given input vector $x_i = (x_{i1}, x_{i2}, \dots, x_{ip})^T$, the output of the j th neuron of the hidden layer may be obtained as:

$$z_{ij} = f_1 \left(\sum_{k=1}^p w_{jk} x_{ik} - b_j \right) = f_1(\text{inp}_{ij}), \quad \text{for } j=1, 2, \dots, l, \quad (2)$$

where $f_1(\cdot)$ is the activation function of the hidden layer, w_{jk} is the weight between the k th net input and j th neuron, and b_j is the bias of the j th neuron. Then the output vector of the network $y_i = (y_{i1}, y_{i2}, \dots, y_{iq})^T$ is given as:

$$y_{iv} = f_2 \left(\sum_{j=1}^l w'_{vj} z_{ij} - b'_v \right) = f_2(\text{inp}_{iv}), \quad \text{for } v=1, 2, \dots, q. \quad (3)$$

Here $f_2(\cdot)$ denotes the activation function, w'_{vj} is the weight between the v th neuron of the output layer and the j th neuron of the hidden layer, and b'_v is the bias of the v th neuron of the output layer. Now, we introduce the robust LTS error criterion, based on the Least Trimmed Squares estimator. The new error function is defined as:

$$E_{LTS} = \sum_{i=1}^h (r_i^2) \quad (4)$$

In this case, $(r_i^2)_{1:n} \leq \dots \leq (r_i^2)_{n:n}$ are ordered squared residuals of the form

$$r_i^2 = \left\{ \sum_{v=1}^q |y_{iv} - t_{iv}| \right\}^2 \quad (5)$$

The trimming constant h must be carefully chosen because it is responsible for the quantity of patterns suspected to be outliers.

We assume, for simplicity, that weights are updated according to the gradient-descent learning algorithm but this can be extended to any other gradient-based algorithm. Then to each weight is added (α denotes a learning coefficient):

$$\Delta w_{jk} = -\alpha \partial E_{LTS} / \partial w_{jk}, \quad (6)$$

$$\Delta w'_{vj} = -\alpha \partial E_{LTS} / \partial w'_{vj}, \quad (7)$$

where

$$\partial r_i / \partial w_{jk} = f_2(inp_{iv}) w'_{vj} f_1(inp_{ij}) x_{ik}, \quad (8)$$

and

$$\partial r_i / \partial w'_{vj} = f_2(inp_{iv}) z_{ij}. \quad (9)$$

The main problem that may occur here is calculating the E_{LTS} derivative. It is not continuous and it can be written as:

$$\frac{\partial \sum_{i=1}^h (r_i^2)_{:n}}{\partial r_i} = \begin{cases} 2r_i & \text{for } r_i^2 \leq (r^2)_{:h} \\ 0 & \text{for } r_i^2 > (r^2)_{:h} \end{cases} \quad (10)$$

As it was experimentally demonstrated, such shape of the derivative function is smooth enough for the BP learning algorithm.

In the use of robust learning algorithms, there exist some problems, concerning mainly the choice of a starting point for the method. In fact, we can divide it into two tasks: choosing initial network parameters, and choosing the right scale estimator. If the initial weights of the network are not properly selected, the learning process may move in the wrong direction and the algorithm may stack in a local minimum. In this case the network performance might become very poor. The scale estimator or its equivalent (here, the trimming constant h) is responsible for the amount of outliers that are to be rejected during the training, it's clearly evident then, that if h is incorrect, gross errors may be regarded as good data and desired points may be discriminated.

Following (Chen and Jain, 1994), we decided to use our LTS robust algorithm after a period of training by the traditional BP algorithm to set the initial parameters. We proposed two strategies of choosing the trimming parameter h . In the first approach we assumed a predefined value of h , depending on expected percentage of outliers in the training data (LTS1). In this case, additional a-priori knowledge of the error distribution is needed, so the strategy is not very useful. The second approach (LTS2) is to choose h by using the median of all errors as:

$$h = |\{r_i : |r_i| < c * \text{median}(|r_i|), i=1 \dots n\}|, \quad (11)$$

where $c=1.483$ for the MAD scale estimate (Huber, 1981). Errors used for calculating h were the errors obtained after the last epoch of the traditional back-propagation algorithm, so the value of h is set constant for the training process.

Simulation Results

The LTS learning algorithm was tested on function approximation tasks. In this paper we present only a few of many different testing situations. The first function to be approximated is $y=x^{-2/3}$ proposed by Chen and Jain (1994), the second one is a two-dimensional spiral given as $x=\sin y$, $z=\cos y$.

To simulate real data containing noise and outliers we used different models, defined as follows:

- Clean data without noise and outliers;
- Data corrupted with the Gross Error Model: $F=(1-\delta)G+\delta H$, where F is the error distribution, $G \sim N(0.0, 0.1)$ and $H \sim N(0.0, 10.0)$ are Gaussian noise and outliers and occur with probability $1-\delta$ and δ (data Type 1);
- Data with high value random outliers (Type 2), proposed in (Pernia-Espinoza et al., 2005) of the form $F=(1-\delta)G+\delta(H_1+H_2+H_3+H_4)$, where $H_1 \sim N(15, 2)$, $H_2 \sim N(-20, 3)$, $H_3 \sim N(30, 1.5)$, $H_4 \sim N(-12, 4)$.
- Data with outliers generated from the Gross Error Model, injected into the input vector x_i (Type 3).

The performances of the traditional backpropagation algorithm (BP), robust LMLS algorithm, and the both variations of the novel robust LTS algorithm, LTS1 and LTS2, were compared.

Looking at the Table 1 we can see that for the clean data of the first task, all algorithms act relatively well. For the data containing gross errors, the two variations of the LTS present the best performance and it is hard to say, which of them is better, while for the data with high value outliers only LTS2 and LMLS ensure good fitting to the testing data, while LTS1, though still better than the BP algorithm, acts rather poor.

For the data containing outliers injected into input, the algorithms LTS1 and LTS2 presented the best per-

Table 1. The mean MSE for the 100 trials for the networks trained to approximate function of one variable

formance and the error of the LTS1 is even over 25% better than for the Lmls and BP.

Results obtained for the second approximation task are, generally, similar. For the data containing outliers, the superiority of the LTS algorithm is clearly evident. The LTS2 acts well also for the high value outliers, showing the lowest error. Besides, for gross errors in the input vector also the LTS1 and LTS2 appear to be the best.

To summarize, one can notice that both LTS algorithms showed performance better than other two algorithms, for the data containing gross errors in the input, as well as in the output vector.

FUTURE TRENDS

Potentially, robust learning algorithms, based on modified error function, can be designed also for training other types of NN structures, such as recurrent or self-organizing networks. Moreover, for the FFNs there is plenty of techniques (adaptive learning rate, transfer functions, etc.) that can be used to make their learning process more robust to outliers.

CONCLUSION

In this paper a novel robust LTS learning algorithm was proposed. As it was experimentally demonstrated, it behaves better than traditional algorithm, and robust Lmls algorithm, in the presence of outliers in the training data. Moreover, it is simultaneously the first robust learning algorithm that takes into account also gross errors injected into the input vector of the training patterns (leverage points). Especially in its second version (LTS2), with median error used to set the trimming constant h , it can be considered as simple and effective mean to increase learning performance on the contaminated data sets. It doesn't need any additional a-priori knowledge of the assumed error distribution to ensure relatively good training results in any conditions. The robust LTS learning algorithm can be easily adapted to many types of neural networks learning strategies.

KEY TERMS

Feedforward Neural Networks: Artificial NN consisting of units arranged in layers with only forward connections to units in subsequent layers.

Gross Errors: Large value errors, often caused by human mistakes, measurement errors, etc.

Leverage Points: Grossly aberrant values of measured or assumed system inputs

Outlier: Observation that is significantly different from majority of data

Robust Estimator: Estimator able to classify data into outliers and clean observations, and to find a reasonable fit to the bulk of data.

Robust Learning Algorithm: NN learning algorithm that can act well even if outliers or leverage points are present in training sets

Robust Statistics: Part of statistics developing methods that should give useful results when certain assumptions (for example of iid light tailed errors) are relaxed

Rough Set–Based Neuro–Fuzzy System

Kai Keng Ang

Institute for Infocomm Research, Singapore

Chai Quek

Nanyang Technological University, Singapore

INTRODUCTION

Neuro-fuzzy hybridization is the oldest and most popular methodology in soft computing (Mitra & Hayashi, 2000). Neuro-fuzzy hybridization is known as Fuzzy Neural Networks, or Neuro-Fuzzy Systems (NFS) in the literature (Lin & Lee, 1996; Mitra & Hayashi, 2000). NFS is capable of abstracting a fuzzy model from given numerical examples using neural learning techniques to formulate accurate predictions on unseen samples. The fuzzy model incorporates the human-like style of fuzzy reasoning through a linguistic model that comprises of if-then fuzzy rules and linguistic terms described by membership functions. Hence, the main strength of NFS in modeling data is universal approximation (Tikk, Kóczy, & Gedeon, 2003) with the ability to solicit interpretable if-then fuzzy rules (Guillaume, 2001). However, modeling data using NFS involves the contradictory requirements of interpretability versus accuracy. Prevailingly, NFS that focused on accuracy employed optimization which resulted in membership functions that derailed from human-interpretable linguistic terms, or employed large number of if-then fuzzy rules on high-dimensional data that exceeded human level interpretation.

This article presents a novel hybrid intelligent Rough set-based Neuro-Fuzzy System (RNFS). RNFS synergizes the sound concept of knowledge reduction from rough set theory with NFS. RNFS reinforces the strength of NFS by employing rough set-based techniques to perform attribute and rule reductions, thereby improving the interpretability without compromising the accuracy of the abstracted fuzzy model.

BACKGROUND

The core problem in soft computing is about bridging the gap between subjective knowledge and objective

data (Dubois & Prade, 1998). There are two approaches of addressing this problem; namely, modeling data in which a function is built to accurately mimic the data, and abstracting data in which a system is built to produce articulated knowledge preferably in natural language form (Dubois & Prade, 1998). The emphasis of the former is on the ability to reproduce what has been observed. Neural networks with their prominent learning capabilities inspired from biological systems are highly suitable in this approach. On the other hand, the emphasis of the latter is on the ability to explain the data in a human interpretable way. Fuzzy systems with the ability of modeling linguistic terms that are expressions of human language are likewise highly effective in this approach. In fuzzy systems, linguistic expressions are formulated from explicit knowledge in the form of if-then fuzzy rules where the linguistic terms of the antecedents and consequents are fuzzy sets. However, the parameters of these linguistic expressions are sometimes difficult to specify and have to be manually tuned. In contrast, although neural networks are capable of learning from data, they are black box models and thus soliciting knowledge from neural networks is not a straightforward task. Hence, a neural network is capable of modeling data, but a user cannot learn from it. On the other hand, a user can learn from a fuzzy system, but it is not capable of learning from data.

Neuro-fuzzy hybridization synergizes these two techniques by combining the human-like reasoning style of fuzzy systems with the learning and connectionist structure of neural networks. Thus, Neuro-Fuzzy Systems (NFS) are gray-box models that are capable of abstracting a fuzzy model from given numerical examples using neural learning techniques. Hence, a Neuro-Fuzzy System learns and at the same time, a user can learn from it as well. However, the use of NFS in abstracting data involves two contradictory requirements in fuzzy modeling: interpretability versus accu-

racy (Casillas, Cordon, Herrera, & Magdalena, 2003). In practice, only one of the two properties prevails. Hence, they can be classified as *linguistic NFS* that are focused on interpretability, mainly using the Mamdani model (Mamdani & Assilian, 1975); and *precise NFS* that are focused on accuracy, mainly using the Takagi-Sugeno-Kang model (Takagi & Sugeno, 1985).

Prevailing research on modeling data using linguistic NFS focused on increasing accuracy as much as possible but neglected interpretability (Casillas et al., 2003). Existing linguistic NFS such as FALCON (Lin & Lee, 1996), POPFNN (Quek & Zhou, 2001) and GenSoFNN (Tung & Quek, 2002) employ the hybrid learning approach to abstract model from numerical data. In this approach, clustering is used in the first stage to generate the membership functions and competitive learning is used to identify the if-then fuzzy rules; followed by supervised learning that uses backpropagation in the final stage to optimize the membership functions. The unconstrained optimization in the final stage increases the accuracy of the abstracted model, but it resulted in membership functions that are derailed from human-interpretable linguistic terms (de Oliveira, 1999). Although the definition of interpretability and its criteria is subjected to controversial discussion, interpretable linguistic variables is often associated with the shape and mutual overlapping of the membership functions (Mikut, Jakel, & Groll, 2005). Nevertheless, formal definition on the semantic properties of interpretable linguistic variables were proposed (Mikut et al., 2005; de Oliveira, 1999); namely, coverage, normalized, convex and ordered. Interpretability is vital to NFS in modeling data because if neglected, they degenerate into black-box models in which the advantages over other methods such as neural networks are lost (Casillas et al., 2003; Mikut et al., 2005). Therefore, abstracting a fuzzy model that is not humanly interpretable derails the fundamental purpose of using NFS.

In addition, a large number of if-then fuzzy rules are required to model high dimensional data, which in turn exceeds the human interpretation capacity (Casillas et al., 2003). This interpretability issue on large number of if-then rules motivates the complexity reduction of NFS. This is similar to the problems encountered by numerical data driven techniques in data mining (Han & Kamber, 2001). These techniques rely on heuristics to guide or reduce their search space horizontally or vertically (Lin & Cercone, 1997). Horizontal reduction is realized by the merging of identical data tuples

or the quantization of continuous numerical values while vertical reduction is realized by feature selection methods. In Linguistic NFS, the former corresponds to the conversion of numerical inputs from a continuous range to a finite number of linguistic terms using membership functions while the latter corresponds to fuzzy if-then rule pruning and reduction. In some existing linguistic neuro-fuzzy systems, vertical reduction is employed by identifying fewer if-then fuzzy rules using certain heuristic threshold (Quek & Zhou, 2001), or by applying pruning based on certainty factors (Tung & Quek, 2002). However, if the number of if-then rules is bounded as a practical limitation through the use of heuristic thresholds, then the universal approximation property is lost (Moser, 1999).

Recently, rough set theory (Pawlak, 1991), one of the methodologies in soft computing, has shown to provide efficient techniques of finding hidden patterns in data (Pawlak, 2002). Rough set-based methods have shown the potential for feasible feature selection with the ability to significantly reduce the pattern dimensionality in neural networks. This motivates the synergy of rough set-based methods with NFS to increase the interpretability of the abstracted model without compromising the accuracy.

ROUGH SET-BASED NEURO-FUZZY SYSTEM

This article presents the hybrid intelligent Rough set-based Neuro-Fuzzy System (RNFS) (Ang & Quek, 2006a), which synergizes the sound concept of knowledge reduction in rough set theory with the human-like reasoning style of fuzzy systems and the learning and connectionist structure of neural networks. Details on the architecture and learning process of the RNFS are described in the following sections.

Architecture of RNFS

The architecture of the RNFS is a five-layer neural network shown in Figure 1. Its architecture is developed using the Pseudo Outer-Product based Fuzzy Neural Network using the Compositional Rule of Inference and Singleton fuzzifier (POPFNN-CRI(S)) (Ang, Quek, & Pasquier, 2003) as a foundation. For simplicity, only the interconnections for the output y_m are shown. Each layer in RNFS performs a specific

Figure 1. Architecture of rough set-based neuro-fuzzy system

fuzzy operation, so the nodes and operations of each layer are noted with a superscript of I to V for clarity. The inputs and outputs of the RNFS are represented as non-fuzzy vector $\mathbf{X} = [x_1, x_2, \dots, x_i, \dots, x_{n_1}]$ and non-fuzzy vector $\mathbf{Y} = [y_1, y_2, \dots, y_m, \dots, y_{n_5}]$ respectively. The fuzzification of the inputs and the defuzzification of the outputs are respectively performed by the input and output linguistic layers respectively while the reasoning mechanism is collectively performed by the condition, rule and consequence layers. Each rule node R_k^{III} in Figure 1 is linked to only one input-label node from each input node and only one output-label node from each output node. The links of rule nodes to the antecedent in the condition layer and the consequent in the consequence layer are mathematically denoted as sets (C^I, D^V) . The antecedent of rule nodes is represented by a set $C^I = \{c_1, c_2, \dots, c_i, \dots, c_{n_1}\}$ where c_i is a condition variable such that $c_i \in \mathbf{IL}_i^{II}$. The set of condition labels c_i can assume is semantically represented by the set of input-label nodes $\mathbf{IL}_i^{II} = \{IL_{i,1}^{II}, IL_{i,2}^{II}, \dots, IL_{i,j}^{II}, \dots, IL_{i,J_i}^{II}\}$ but a computational notation of $\mathbf{IL}_i^{II} = \{1, 2, \dots, j, \dots, J_i\}$ is used in this article. Similarly, the consequent of rule nodes is represented by a set $D^V = \{d_1, d_2, \dots, d_m, \dots, d_{n_5}\}$

where d_m is a consequent variable such that $d_m \in \mathbf{OL}_m^{IV}$. The set of consequent labels d_m can assume is semantically represented by the set of output-label nodes $\mathbf{OL}_m^{IV} = \{OL_{m,1}^{IV}, OL_{m,2}^{IV}, \dots, OL_{m,l}^{IV}, \dots, OL_{m,L_m}^{IV}\}$ but a computational notation of $\mathbf{OL}_m^{IV} = \{1, 2, \dots, l, \dots, L_m\}$ is used in this article. The specific links of a rule node R_k^{III} to the antecedent in the condition layer and the consequent in the consequence layer is denoted as (C_k^I, D_k^V) .

The novel characteristics of RNFS are:

- *Vertical reduction of if-then fuzzy rules* – is performed in RNFS in which the Rough Set-based Pseudo Outer-Product (RSPOP) algorithm (Ang & Quek, 2005) is used to identify if-then fuzzy rules, perform attribute reduction and rule reduction using rough set-based knowledge reduction. This vertical reduction process is performed autonomously without relying on user-defined heuristic thresholds to identify fewer if-then fuzzy rules.
- *Supervised learning* – is employed in RNFS in which the Supervised Pseudo Self-Evolving Cerebellar (SPSEC) algorithm (Ang & Quek, 2006a) is used to generate membership functions and the RSPOP algorithm is used to identify the if-then

- fuzzy rules, instead of using backpropagation or hybrid learning approach.
- Automated model abstraction* – is performed by RNFS without the need of user-defined parameters in the neural learning algorithms that generate the membership functions and identify the if-then fuzzy rules. Thus, it does not require specialized skills and knowledge.

Supervised Learning Process of RNFS

The RNFS employs a novel supervised learning approach that comprises mainly of two algorithms: the SPSEC (Ang & Quek, 2006a) that generates membership functions, and the RSPOP (Ang & Quek, 2005) that identifies the if-then fuzzy rules.

Figure 2 illustrates the neural learning process of the Supervised Pseudo Self-Evolving Cerebellar (SPSEC) membership function generation algorithm (refer to (Ang & Quek, 2006a) for details on the algorithm). Figure 2(a) shows steps 1-2 where SPSEC constructs a cerebellar structure with m regularly spaced neurons that spans the input space, in which the cerebellum is the part of our brain that is involved in learning of motor skills and provides precise coordination of motor control for our body parts (Kandel, Schwartz, & Jessell, 1995). These steps model the first-stage development process of our nervous system where the basic architecture and coarse connection patterns are laid out without any activity-dependent processes (Kandel et al., 1995). Figure 2(b) shows steps 3-4, where SPSEC performs structural learning by performing a one-pass weight learning using Gaussian neighborhood learning to determine the distribution of the training data, and pseudo self-evolves this cerebellar structure by identifying surviving neurons with high trophic factor whose weights form a peak while the remaining neurons are removed. These steps model the second-stage development process of our nervous system where initial architecture is refined in activity-dependent ways (Kandel et al., 1995). Figure 2(c) show step 5, where the surviving neurons' weights are the parameters of the resulting Gaussian membership function that reconcile with the semantics of interpretable linguistic variables.

The SPSEC algorithm (Ang & Quek, 2006a) is capable of generating effective membership functions that reconcile with semantics of interpretable linguistic variables; namely, coverage, normalized, convex and

ordered (Mikut et al., 2005). The membership functions generated do not require a further optimization process used in the hybrid learning approach to increase the accuracy of the abstracted model. Eliminating the burden of further optimization process ensures that the membership functions generated do not deviate from human-interpretable terms.

Figure 3 illustrates the rough-set based knowledge reduction process of the Rough set-based Pseudo Outer-Product (RSPOP) if-then fuzzy rule identification algorithm (refer to (Ang & Quek, 2005) for details on the algorithm). Figure 3(a) shows an example of a set of influential if-then fuzzy rules identified by the *RSPOP Rule Identification* steps using Hebbian learning (Hebb, 1949). Figure 3(b) shows the if-then fuzzy rules that are reduced by the *RSPOP Attribute Reduction* steps using rough set-based knowledge reduction (Pawlak, 1991). Figure 3(c) shows the if-then fuzzy rules that are further reduced by the *RSPOP Rule Reduction* steps using rough set-based knowledge reduction (Pawlak, 1991).

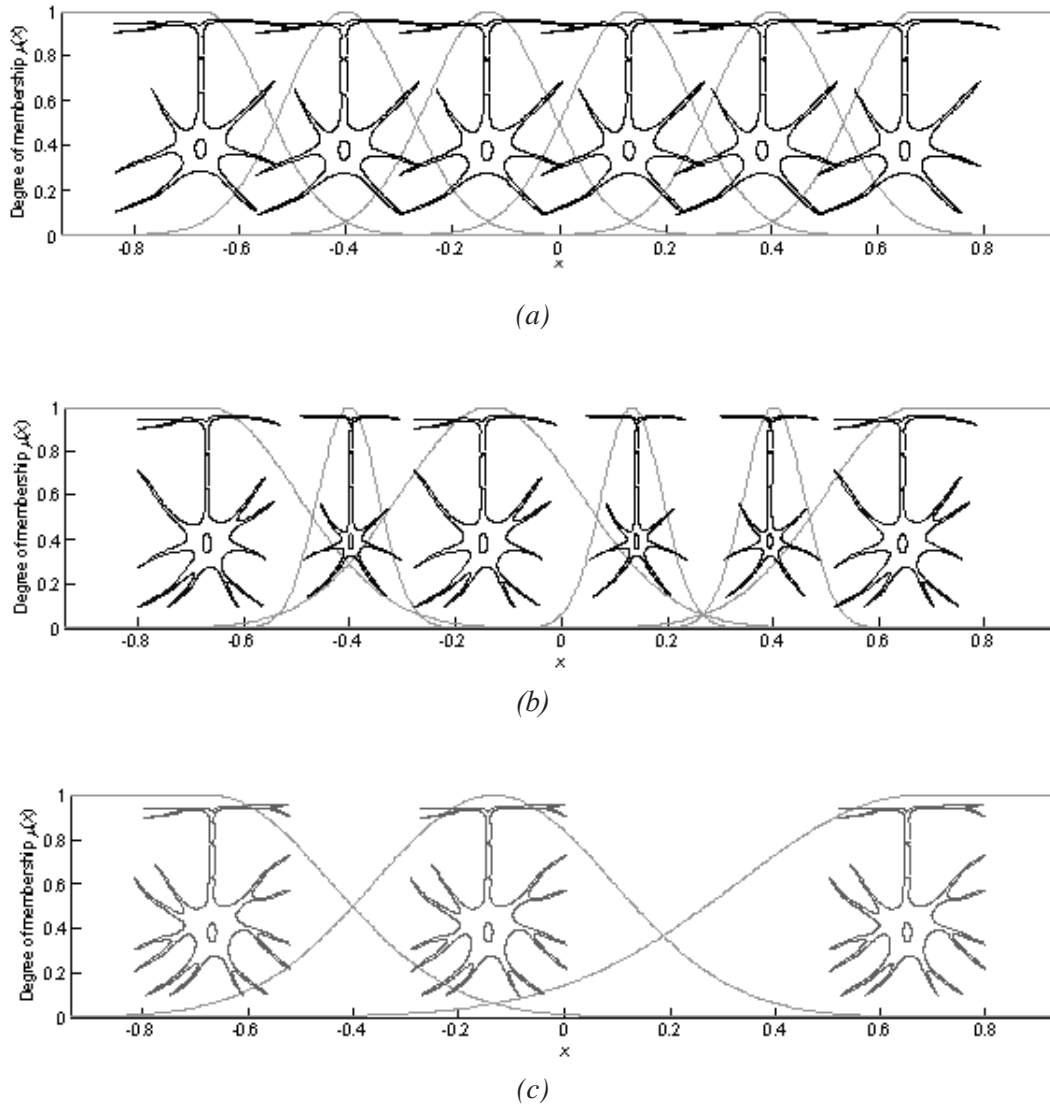

The numbers 0-4 in Figure 3 that represent condition and consequent labels in Figure 1 do not show that the if-then fuzzy rules identified are interpretable. To illustrate the intuitiveness of the if-then fuzzy rules identified, an example on the mapping of semantic labels to each condition and consequent labels is illustrated in Table 1.

The example in Figure 3 and Table 1 shows that the RSPOP algorithm is capable of identifying fewer but effective if-then fuzzy rules that facilitates human interpretation. The fewer number of if-then fuzzy rules identified is effective because RSPOP integrates the knowledge reduction technique in rough set theory with the Hebbian learning technique to identify non-redundant if-then fuzzy rules. The accuracy of the abstracted model is not compromised because only reducts that do not deteriorate the accuracy of the abstracted model are reduced by RSPOP.

FUTURE TRENDS

The proposed RNFS architecture is based on the synergy of the sound concept of knowledge reduction in rough set theory with NFS (Ang & Quek, 2005). Existing NFS are not capable of abstracting accurate and interpretable models from high-dimensional data without first performing feature selection to reduce

Figure 2. SPSEC neural learning process (a) Steps 1-2 constructs a basic cerebellar structure consisting of regularly spaced neurons, (b) Steps 3-4 active neurons stabilize through the update of trophic factors while competitors die, (c) Steps 5 surviving neurons form the resulting membership functions that reconcile with semantics of linguistic variables

the data dimensionality to a manageable quantity. The synergy of Rough set-based knowledge reduction strengthens and empowers NFS with the potential application on high-dimensional data such as microarray gene expressions and function Magnetic Resonance Imaging (fMRI). Hence, further investigation on the adequacy of abstracting high-dimensional data using RNFS should be carried out and compared against other prevailing approaches.

In addition, existing NFS relied on user-defined parameters to avoid over-fitting the training data in order to generalize well on unseen test data. This issue is known as overfitting avoidance and Occam's razor in pattern recognition literature (Duda, Hart, & Stork, 2001). Although the RNFS is capable of autonomously abstracting a model from numerical data without requiring user-defined parameters, preliminary investigations

Figure 3. RSPOP rule identification process (a) RSPOP identifies an initial set of if-then fuzzy rules identified using Hebbian learning; (b) RSPOP performs attribute reduction on the initial set of if-then fuzzy rules using rough set-based knowledge reduction; and (c) RSPOP performs a further rule reduction on the if-then fuzzy rules

revealed that RNFS may possibly abstract a model that overfits the training data. Therefore, further studies on how to avoid overfitting the training data by RNFS without relying on user-defined parameters should be carried out.

CONCLUSION

This article presents a Rough set-based Neuro-Fuzzy System (RNFS), which is a hybrid intelligent system that synergizes the sound concept of knowledge reduction in rough set theory with the human-like reasoning style of fuzzy systems and the learning and connectionist structure of neural networks. The main strength of Neuro-Fuzzy hybridization is universal approximation

(Tikk et al., 2003) with the ability to solicit interpretable if-then fuzzy rules (Guillaume, 2001). Rough set-based Neuro-Fuzzy hybridization strengthens it further by improving the interpretability as well as the accuracy of existing Neuro-Fuzzy hybridization. Recently, the Rough set-based Neuro-Fuzzy approach of abstracting models from data has been successfully applied to various applications such as traffic flow prediction (Ang & Quek, 2005), financial stock trading (Ang & Quek, 2006b) and the classification of biomedical data (Ang & Quek, 2006a). Hence, the potential of RNFS is exciting as it improves the interpretability of NFS without compromising the accuracy of the abstracted model.

KEY TERMS

Attribute Reduction: The process whereby dispensable attributes are removed from the knowledge while maintaining knowledge consistency.

Fuzzy System: A system whose variables range over states that are fuzzy sets. A fuzzy system is capable of modelling the linguistic terms that are expressions of human language.

Knowledge Reduction: Knowledge reduction in rough set theory comprises of attribute reduction and partial attribute reduction.

Neural Network: A network of many simple processors called units or neurons. A neural network is capable of learning the nonlinear relationships in data.

Neuro-Fuzzy System: A hybrid intelligent system that synergizes the human-like reasoning style of fuzzy systems with the learning and connectionist structure of neural networks.

Rough Set: A rough set is a formal approximation of a crisp set in terms of a pair of sets that give the lower and upper approximation of the original set

Rough Set-Based Neuro Fuzzy System: A hybrid intelligent system that synergizes the sound concept of knowledge reduction in rough set theory with neuro-fuzzy systems.

Rule Reduction: The process of partial attribute reduction whereby dispensable attributes from certain rules of the knowledge is removed while maintaining knowledge consistency.

Rule Engines and Agent-Based Systems

Agostino Poggi

Università di Parma, Italy

Michele Tomaiuolo

Università di Parma, Italy

INTRODUCTION

Expert systems are successfully applied to a number of domains. Often built on generic *rule-based systems*, they can also exploit optimized algorithms.

On the other side, being based on loosely coupled components and peer to peer infrastructures for asynchronous messaging, *multi-agent systems* allow *code mobility*, adaptability, easy of deployment and reconfiguration, thus fitting distributed and dynamic environments. Also, they have good support for domain specific *ontologies*, an important feature when modeling human experts' knowledge.

The possibility of obtaining the best features of both technologies is concretely demonstrated by the integration of *JBoss Rules*, a rule engine efficiently implementing the *Rete-OO algorithm*, into *JADE*, a *FIPA-compliant multi-agent system*.

BACKGROUND

Rule Engines

The advantages of *rule-based systems* over procedural programming environments are well recognized and widely exploited, above all in the context of business applications. Working with rules helps keeping the logic separated from the application code: it can be modified by non-developers and, being centralized in one point, it can be analyzed and validated. *Rule engines* are often well optimized, being able to efficiently reduce the number of rules to match against the updated knowledge base.

Rule-based systems can also be augmented with ideas and techniques developed in other research fields, leading for example to fuzzy rule-based systems, which exploit fuzzy logic to deal with imprecision and uncertainty about the knowledge base. Moreover,

sometimes these systems are coupled with genetic algorithms and evolutionary programming to generate complex classifiers.

One of the most notable application of rule-based systems are *expert systems*, where the rule set is a representation of an expert's knowledge. In such systems, the AI (Artificial Intelligence) is supposed to perform in a similar manner to the expert, when exposed to the same data.

Among the different mechanisms to implement a rule-engine, *Rete algorithm* (Forgy, 1982) has gained more and more popularity, mainly thanks to the high degree of optimization that can be obtained. At NASA Johnson Space Center, *Rete algorithm* was implemented in a whole generation of rule engines. OPS5 was soon replaced by its descendant, ART, and in 1984 by the more famous CLIPS.

Nowadays, one of the most widespread engines implementing *Rete* is *Jess* (Friedman-Hill, 2000), at first developed as a Java port of CLIPS at Sandia National Laboratories in late 1990s. *Jess* has also been widely adopted by the agent community to realize rule-based agent systems (Cardoso, 2007).

A different yet promising rule-engine is *JBoss Rules* (Proctor, Neale, Frandsen, Griffith & Tirelli, 2007), formerly *Drools*. It is a quite new, but already well known, freeware tool implementing so-called *Rete-OO algorithm*.

Its open-source availability is a clear advantage over *Jess*, but an even greater advantage is due to the implementation of a particular adaptation of the *Rete algorithm* for the object-oriented world, rather than a literal one. This way, the burden of integrating the rule-engine and application rules with existing external objects is greatly reduced. In fact, *JBoss Rules* uses plain Java objects to represent rules and facts, which can be modified through their public methods and properties. Rules can be specified through an appropriate syntax, or through xml structures, and their conditions and consequences can be expressed using different scripting

Figure 1. Basic example from the JBoss Rules handbook

```

package org.drools.examples

import org.drools.examples.HelloWorldExample.Message;

rule "Hello World"
when
    m : Message( status == Message.HELLO, message : message )
then
    System.out.println( message );
    m.setMessage( "Goodbye cruel world" );
    m.setStatus( Message.GOODBYE );
    update( m );
end

rule "GoodBye"
no-loop true
when
    m : Message( status == Message.GOODBYE, message : message )
then
    System.out.println( message );
end

```

languages, as Python, Groovy and Java. Instead *Jess* only accepts rules written in the CLIPS language, thus requiring developers to learn a new Lisp-like language and deploy additional efforts to adapt it to their object-oriented development environment.

Agent-Based Systems

Multi-agent systems (MAS) show some complementary features which can be useful in many rule-based application, above all asynchronous interaction protocols and semantic languages. In multi-agent systems, in fact, many intelligent agents interact with each other. The agents are considered to be autonomous entities, and their interactions can be either cooperative or selfish (i.e. they can share a common goal, as in a production line, or they can pursue their own interests, as in an open marketplace).

The *Foundation for Intelligent Physical Agents* (FIPA, 2002) develops open specifications, to support interoperability among agents and agent-based applications. Specifications for infrastructures include a communication language for agents, services for agents, and they anticipate the management of domain-specific

ontologies. A set of application domains is also specified, including personal assistance for travels, network management, electronic commerce, distribution of audio-visual media. At the core of FIPA model there's the communication among agents; in particular it describes how the agents can exchange semantically-meaningful messages with the aim of completing activities required by the overall application.

Various implementations of FIPA-compliant platforms exist (FIPA implementations, 2003). Among them, *JADE* (Bellifemine, Caire, Poggi & Rimassa, 2003) has gained popularity during the years, while more and more core functionalities and third-party plug-ins were being developed. Currently it supports most of the infrastructure related *FIPA* specifications, like transport protocols, message encoding, and white and yellow pages agents. Moreover, it has various tools that ease agent debugging and management.

The possibility of using rules to realize agent systems seems to be promising. On the one hand, rules have been shown suitable to define abstract and real agent architectures and have been used for realizing so-called "*rule-based agents*", that is, agents whose behaviour and/or knowledge is expressed by means of

rules (Shoham, 1993) (Rao, 1996) (Hindriks, de Boer, van der Hoek & Meyer, 1998) (Schroeder & Wagner, 2000). On the other hand, given that rules are easy and suitable means to realize reasoning, learning and knowledge acquisition tasks, rules have been used into so-called “*rule-enhanced agents*”, that is, agents whose behaviour is not normally expressed by means of rules, but that use a rule engine as an additional component to perform specific reasoning, learning or knowledge acquisition tasks (Gutknecht, Ferber & Michel, 2000) (Katz, 2002). Both the approaches have some advantages and disadvantages. *Rule-based agents* provide all the advantages of *rule-based systems* and a uniform way to program them, but their performance is inadequate for some kinds of applications. *Rule-enhanced agents* allow the use of different programming paradigms; therefore, it is possible to use the most appropriate paradigm for the realization of the different tasks both to simplify the development and to satisfy the performance requirements, but there is an additional cost for the management of the integration/synchronization of such heterogeneous tasks. With behaviour-based agents, as in *JADE*, the *rule engine* can be integrated into an agent as a behaviour. This approach can alternatively guarantee the advantages of full *rule-based agents* or the ones of *rule-enhanced agents*. In facts, both procedural and rule-based behaviours can be seamlessly added to each deployed agent, according to the application features and requirements.

Code Mobility and Security

Mobile code proves useful in many contexts (Fuggetta, Picco & Vigna, 2000), thanks to its ability to overcome network latency, reduce network load, allow asynchronous execution and autonomy, adapt dynamically, operate in heterogeneous environments, provide robust and fault-tolerant behaviours. *Mobile code* technologies vary from applets and other dynamic code downloading mechanisms, to full mobile agent systems, adhering to models as code on demand, remote evaluation, mobile agents. When a rule engine is integrated into a multi-agent system, two different cases are possible: asking a remote agent to execute a task, or to apply a new rule to its knowledge base. While mobile rules falls into the class of asynchronous requests with deferred execution, instead mobile tasks fall into the synchronous class. In both cases the moved entity is a fragment of code, to

be interpreted by a scripting engine on the target agent, and not a complete thread of execution.

The different *security threats* that a *mobile code* system could face, and the relevant security countermeasures that could be adopted, should also be analyzed. In (Jansen & Karygiannis, 2000) two different classes of attacks are identified, depending on their target: the ones targeting the executing environment of mobile code, and the ones targeting the code itself. While the fact that mobile code could pose threats to its hosting environment is widely accepted, instead often the possibility to face threats against the hosted code is not taken into consideration. This is certainly due to a lack of effective countermeasures to prevent the hosting environment from stealing data and algorithms from the mobile code, from executing it too slowly to be effective, altering its execution flow, or stopping its execution. Experimental algorithms exist to at least detect “a posteriori” this type of threats, including partial result encapsulation, mutual itinerary recording, itinerary recording with replication and voting, execution tracing. Some algorithms even try to prevent some types of attacks to the code hosted in malicious environments, but their real effectiveness has yet to be proved; these include environmental key generation, computing with encrypted functions, and obfuscated code (sometimes called time limited blackbox). On the other hand, potential threats posed by hosted code include masquerading, denial of service, eavesdropping, and alteration. Available security countermeasures to protect the execution environment against potentially malicious mobile code often rely on algorithms to prevent attacks, like software-based fault isolation, safe code interpretation, authorization and attribute certificates, proof carrying code. Other techniques are focused on detecting attacks to the environment and tracing them to their origin; these include state appraisal, signed code, path histories.

Systems based on Java can leverage on the security means provided by the virtual machine, and extend them as needed. In particular, it is possible to define precise protection domains on the basis of *authorization certificates* (Poggi, Tomaiuolo & Vitaglione, 2004). These certificates, attached to mobile code, list a set of granted permissions and are signed by local resource managers. Access rights can also be delegated to other agents, to allow them to complete the requested tasks or to achieve delegated goals (Somacher, Tomaiuolo & Turci, 2002). Finally, masquerading and alteration

threats can be prevented by establishing authenticated, signed and encrypted channels between remote components of the system.

INTEGRATION OF RULES AND AGENTS

Among the different implementations of *rules-enhanced multi-agent systems*, the analysis Drools4JADE (Drools4JADE) can be particularly interesting, as the system resulted from the evaluation of existing technologies in various fields. In fact, the purpose of this project was to not start from scratch, to develop of a totally new agent platform, but instead to build on existing solutions, which already demonstrated to be a sound layer on which more advanced functionalities could be added.

In this case, the chosen agent system is *JADE* (Bellifemine, Caire, Poggi & Rimassa, 2003). Its successful adoption in large international projects, like *Agentcities* (Poggi, Tomaiuolo & Turci, 2004), *openNet* and *TechNet* (Willmott, 2004), proved it to be preferable to other solutions, thanks to its simplicity, flexibility, scalability and soundness. As already argued, its integration with an open source object-oriented rule engine, as *JBoss Rules*, in many contexts is to be favoured against the more traditional *JADE-Jess* couple (Cardoso, 2007).

FIPA Interface to the Rule Engine

To the rich features of *JBoss Rules*, an agent environment can add above all the support for communications through ACL (Agent Communication Language) messages, typical of *FIPA* agents. Rules can reference ACL messages in both their precondition and consequence fields. Moreover, a complete support to manipulate facts and rules on rules-enhanced agents through ACL messages can be provided.

Inside the *JBoss Rules* environment a rule is represented by an instance of the Rule class: it specifies all the data of the rule itself, including the pre-conditions making the rule valid and the actions to be performed as consequence of the rule. When a rule is scheduled for execution, i.e. all its preconditions are satisfied by asserted facts, the engine creates a new instance of the embedded scripting environment, set the needed variables inside it and invokes the interpreter to execute the code contained in the consequence section of the rule.

In Drools4JADE, rules-enhanced agents expose a complete API to allow the manipulation of their internal working memory through ACL requests. Their *ontology* defines requests to add rules, assert, modify and retract facts. All these requests must be joined with an *authorization certificate*. Only authorized agents, i.e. the ones that show a certificate listing all needed permissions, can perform requested actions. Moreover, the accepted rules will be confined in a specific protection domain, instantiated according to their own *authorization certificate*.

Security Issues

Mobility of rules and code among agents paves the way for really adaptive applications, but it cannot be fully exploited if security issues aren't properly addressed. The security means implemented in Drools4JADE greatly benefit from the existing infrastructure provided by the underlying Java platform and by *JADE*. The security model of *JADE* deals with traditional user-centric concepts, as principals, resources and permissions. Moreover it provides means to allow delegation of access rights among agents, and the implementation of precise protection domains, by means of authorization certificates.

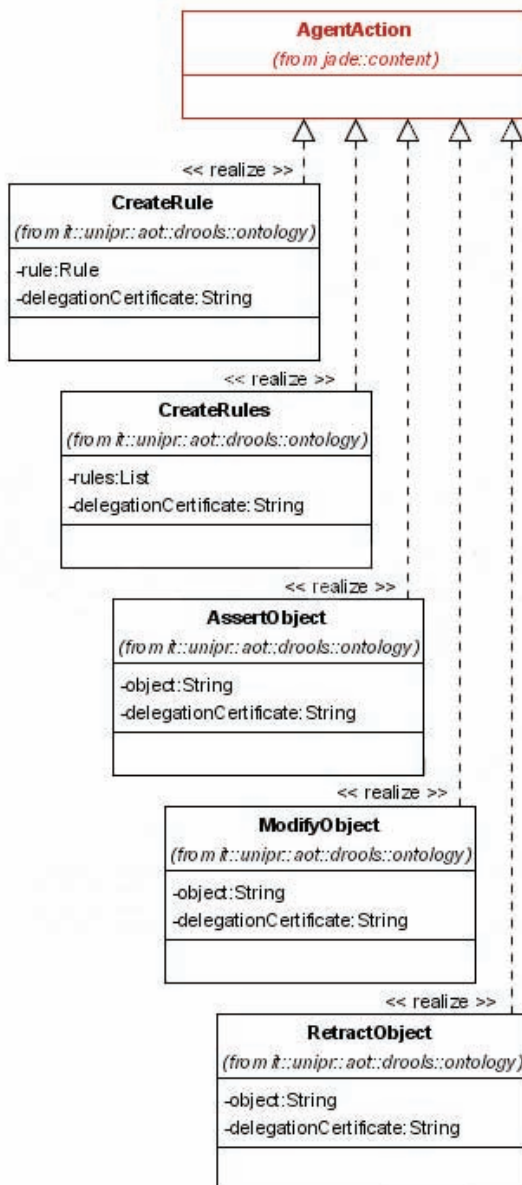

In the security framework of *JADE*, a principal represents any entity whose identity can be authenticated. Principals are bound to single persons, departments, companies or any other organizational entity. Also single agents are bound to a principal; with respect to his own agents, a user constitutes a parent principal, thus allowing to grant particular permissions to all agents launched by a single user.

Resources that *JADE* security model cares for include those already provided by security Java model (i.e. file system, network connections, environment variables, database connections). Resources typical of multi-agent systems, to be protected against unauthorized accesses, include agents themselves and their executing environment.

A permission represents the capability to perform actions on system resources. To take a decision while trying to access a resource, access control functions compare permissions granted to the principal with permissions required to execute the action; access is allowed if all required permissions are owned.

When an agent is requested to accept a new rule or task, a first access protection involves authenticat-

Figure 2. Actions supported by rules-enhanced agents

ing the requester and checking the authorization to perform the action; i.e.: can the agent really add a new rule, or submit a task, to be performed on its behalf? To perform these tasks, the requester needs particular permissions.

Moreover, to exploit the full power of task delegation and rule mobility, the target agent should be able to restrict the set of resources made accessible to mobile

code. Agents should be provided means to delegate not only tasks, but even access rights needed to perform those tasks. This is exactly what is made possible through the security package of JADE, where distributed security policies can be checked and enforced on the basis of signed *authorization certificates*.

In this kind of systems, every requested action can be accompanied with a certificate, signed by a local resource manager, listing the permissions granted to the requester. Permissions can be obtained directly from a policy file, or through a delegation process. Through this process, an agent can further delegate a set of permissions to another agent, if it can prove the possession of those permissions.

The final set of permissions received through the request message, can finally be used by the servant agent to create a new protection domain to wrap the mobile code during its execution, protecting the access to system, as well as application, resources.

FUTURE TRENDS

A system architecture founded on *rule engines* and *multi-agent systems* is a good starting point to build a fully distributed environment, where the distributed knowledge can include both data and code. For example it can be used to realize systems for distributed signals and alarms handling, network management etc.

The development of advanced grid features, as transparent and reconfigurable functions for dynamic load balancing, distribution of facts and rules among remote engines, failure detection and recovery, could add even greater value to the system, paving the way for the development of distributed computing environments founded on networks of *FIPA* agents and platforms.

CONCLUSION

The integration of an object-oriented *rule engine* and a scripting engine into an agent development framework can provide many advantages. The resulting system joins the soundness of a platform for distributed *multi-agent systems*, with the expressive power of rules and the ability to adapt to changing conditions granted by *mobile code*.

Of course, the development of real world applications poses serious security requirements, which can

be faced by means of detailed security policies and delegation of *authorizations* through signed *certificates*. Application areas include, but certainly are not limited to, e-learning, e-business, service-composition, network management.

KEY TERMS

Authorization Certificate: A digital document that describes a permission from the issuer to use a service or a resource that the issuer controls or has access to use. Usually it is signed by means of a public key algorithm. The permission in some case can also be delegated.

Expert System: Encodes the knowledge of an expert into the rule set of a rule-based system. When exposed to the same data, the expert system AI will perform in a similar manner to the expert.

Multi-Agent System: A software system based on the interaction of several agents. Such agents could not have all data or all resources needed to achieve an

objective and need to collaborate with other agents. In this case, data is decentralized and execution is asynchronous. Earlier, related fields include Distributed Artificial Intelligence (DAI) and distributed problem solving (DPS).

Ontology: An explicit specification of a conceptualization, formally describing the entities involved in a particular domain and the relationships among them.

Production System (or production rule system): a rule-based system whose rules (termed productions) consist of two parts: a sensory precondition (or “if” statement) and an action (or “then”). If a production’s precondition (left-hand side or LHS) matches the current state of the world, then the production is said to be triggered. If a production’s action is executed, it is said to have fired. The rule interpreter must provide a mechanism for prioritizing productions when more than

one is triggered. Rule interpreters generally execute a forward chaining algorithm for selecting productions to execute.

Rule-Based System: Created using a set of assertions, which collectively form the “working memory”, a database which maintains data about current state or knowledge, a set of rules, specifying how to act on the assertion set, and a rule-engine or interpreter. Basically, rule-based systems can consist of little more than a set of if-then statements, but provide the basis for so-called “expert systems”.

Software Agent: A software entity being able to act with a certain degree of autonomy, in order to accomplish tasks on behalf of its user. While objects are defined in terms of methods and attributes, agents are defined in terms of their behaviours. Usually agents show persistence, autonomy, social ability, reactivity.

Sequence Processing with Recurrent Neural Networks

Chun-Cheng Peng

University of London, UK

George D. Magoulas

University of London, UK

INTRODUCTION

Sequence processing involves several tasks such as clustering, classification, prediction, and transduction of sequential data which can be symbolic, non-symbolic or mixed. Examples of symbolic data patterns occur in modelling natural (human) language, while the prediction of water level of River Thames is an example of processing non-symbolic data. If the content of a sequence will be varying through different time steps, the sequence is called *temporal* or *time-series*. In general, a temporal sequence consists of nominal symbols from a particular alphabet, while a time-series sequence deals with continuous, real-valued elements (Antunes & Oliverira, 2001). Processing both these sequences mainly consists of applying the current known patterns to produce or predict the future ones, while a major difficulty is that the range of data dependencies is usually unknown. Therefore, an intelligent system with memorising capability is crucial for effective sequence processing and modelling.

A recurrent neural network (RNN) is an artificial neural network in which self-loop and backward connections between nodes are allowed (Lin & Lee 1996; Schalkoff, 1997). Comparing to feedforward neural networks, RNNs are well-known for their power to memorise time dependencies and model nonlinear systems. RNNs can be trained from examples to map input sequences to output sequences and in principle they can implement any kind of sequential behaviour. They are biologically more plausible and computationally more powerful than other modelling approaches, such as Hidden Markov Models (HMMs), which have non-continuous internal states, feedforward neural networks and Support Vector Machines (SVMs), which do not have internal states at all.

In this article, we review RNN architectures and we discuss the challenges involved in training RNNs

for sequence processing. We provide a review of learning algorithms for RNNs and discuss future trends in this area.

BACKGROUND

One of the first RNNs was the *avalanche network* developed by Grossberg (1969) for learning and processing an arbitrary spatiotemporal pattern. Jordan's *sequential network* (Jordan, 1986) and Elman's *simple recurrent network* (Elman, 1990) were proposed later.

The first RNNs did not work very well in practical applications, and their operation was poorly understood. However, several variants of these models were developed for real-world applications, such as robotics, speech recognition, music composition, vision, and their potential for solving real-world problems has motivated a lot of research in the area of RNNs.

Current research in RNNs has overcome some of the major drawbacks of the first models. This progress has come in the form of new architectures and learning algorithms, and has led in a better understanding of the RNNs' behaviour.

ARCHITECTURES OF RECURRENT NETWORKS

In the literature, several classification schemes have been proposed to organise RNN architectures starting from different principles for the classification, i.e. some consider the loops of nodes in the hidden layers, while others take the types of output into account. For example, they can be organised into *canonical RNNs* and *dynamic MLPs* (Tsoi, 1998a); *autonomous converging* and *non-autonomous non-converging* (Bengio et al., 1993); *locally* (receiving feedback(s) from the

same or directly connected layer), *output feedback*, and *fully connected* (i.e. all nodes are capable to receive and transfer feedback signals to the other nodes, even within different layers) RNNs (dos Santos & Zuben, 2000); *binary* and *analog* RNNs (Orponen, 2000).

From mathematical point of view (Kremer, 2001), assuming that y and z are respectively the response of the output layer and the output of the hidden layer, a static feedforward neural network can be formulated as follows:

$$y = \phi(\mathbf{W}^u z + b^u) \quad (1)$$

$$z = \phi(\mathbf{W}^l x + b^l), \quad (2)$$

where $f(\bullet)$ denotes nonlinear activation function, \mathbf{W}^l and \mathbf{W}^u the weights of the hidden layer and the output layer, x the input vector, and b the biases. This general form could be easily transformed to describe a Feed-Forward Time-Delayed (FFTD) RNN by substituting the following delayed equations with time index t ,

$$y(t) = \phi(\mathbf{W}^u z(t) + b^u) \quad (3)$$

$$z(t) = \phi(\mathbf{W}^l s(t) + b^l) \quad (4)$$

$$s(t) = \{x(t) \oplus x(t-1) \oplus \dots \oplus x(t-d)\}, \quad (5)$$

where $s(t)$ denotes the state vector at time t , \oplus the Cartesian product, d the number of delays. By adding a feedback connection from the hidden layer to the delay unit then Eq. (4) can be stated as

$$z(t) = \phi(\Lambda z(t-1) + \mathbf{W}^l x(t) + b^l), \quad (6)$$

where Λ is a diagonal matrix, which describes an Elman-type RNN.

For the Nonlinear Autoregressive Network with Exogenous Inputs (NARX) the state is described as

$$s(t) = \{x(t) \oplus x(t-1) \oplus \dots \oplus x(t-d+1)\} \oplus \{y(t-1) \oplus y(t-2) \oplus \dots \oplus y(t-m)\}, \quad (7)$$

where m is the number of output feedbacks. The formulations of a fully RNN can also be derived by combining Eqs. (3) and (7) with the following one:

$$z(t) = \phi(\Lambda z(t-1) + \mathbf{W}^l s(t) + \mathbf{W}^l x(t) + b^l). \quad (8)$$

Table 1 provides an overview of the various architectures and of the relevant literature.

LEARNING ALGORITHMS FOR RECURRENT NETWORKS

With regards to training RNNs and storing information in their internal representations, Gradient Descent-based learning algorithms (GD) are the most commonly applied methods, even though it has been claimed that GD has some drawbacks (Bengio et al., 1994). Firstly, when the delays or recursive connections are very deep, i.e. when long-term memory is required, the backpropagation error may be vanished and the training process could become inefficiently. Secondly, the most common way to apply GD algorithms into RNN is to unfold the recursive layers and train the whole network as a feedforward network. Another drawback is that the generalisation is highly affected by the samples in the training dataset. In temporal processing it is difficult to extract or prepare negative samples from a given

Table 1. Classification summary of RNNs

| Recurrence | Globally | Locally | Fully | Partially |
|------------|--|---|-----------------|--------------------------------|
| Reference | Brouwer (2005) Kremer & Kolen (2000) Puskorius & Feldkamp (1994) | Assaad et al. (2005) Boné & Cardot (2005) Sperduti & Starita (1997) Temurtasm et al. (2004) Tiño & Mills (2005) | Pedersen (1997) | All, except Pedersen (1997) |

training dataset and the specific RNN then predicts or classifies new coming samples according to the learned knowledge only.

In (Bengio et al., 1993), besides Backpropagation Through Time (BPTT) and real-time gradient computation, approaches with space and/or time locality are also reviewed. However, local algorithms can be applied to some specific local feedback RNNs and for short-term memorisation only due to their inherent representation capabilities. The inefficiency of GD in learning long-term dependencies is mainly because previous information is treated initially as noise and gradually is ignored (Bengio et al., 1993; Bengio et al., 1994). Therefore two alternative algorithms are revised and discussed in Bengio's works: the time-weighted pseudo-Newton and the discrete error propagation. The former applies the unfolding method to the pseudo-Newton optimisation and the later considers the limited case of propagation only; it has to be verified whether this would work on other more general situation or not.

Two types of learning algorithms are discussed in (Pearlmutter, 1995): the *fixed point*, and the *nonfixed point*. Well-known algorithms such as BPTT and Real-time Recurrent Learning (RTRL) are included in this classification and a way of introducing time constants and time delays is also suggested. The method of extended RTRL (eRTRL) is also discussed and other relevant approaches, such as Elman nets, Jordan nets, the moving targets method, feedforward nets with state, teach forcing in continuous time and Kalman filter are reviewed. Pearlmutter (1995) also compares the complexity both in time and space, and discusses the learning mode, stability and locality of these algorithms.

For fully connected hidden layer networks and dynamic MLPs, Tsoi (1998b) has investigated two first-order gradient learning algorithms. This work discusses some drawbacks of these methods, such as slow convergence and generalisation, and derives two 2nd-order approaches to speed up the convergence and to tackle the issue of weight pruning; it also provides a discussion on output sensitivity. The lower sensitivity of output to a specific adjustable parameter, the better performance of the network is. Although the related formulas are well defined in this work (Tsoi, 1998b), there is still a crucial constant which is used to set the level of sensitivity that should be defined by the users. Quasi-2nd order methods, such as conjugate gradient, scaled conjugate gradient and Newton approach, have

been also mentioned and pointed out as suitable only for batch training, while Kalman filter and extended Kalman filter are classified as 2nd-order GD based learning algorithms, which can be used under online mode, where extended Kalman filter could be used to prune weights from a RNN.

Kremer (2001) reviews 14 kinds of memories used in spatiotemporal connectionist networks, capable of computing the state vectors, and provides a general formulation for computing output vectors. The author also summaries 10 different kinds of updating rules, such as full GD, truncated GD, autoassociative GD, and stack learning. It examines three open issues: the temporal credit assignment, the representation capabilities and the knowledge encoding.

From the point of view of time-series modelling, Kolehmainen (2003) covers BPTT and RTRL for learning RNNs, while Dietterich (2002) suggests BPTT. In the same vein with Baldi (1993) and Pearlmutter (1995), fixed point networks are also considered and five relative algorithms, such as BPTT and GD learning of time constants, gains and delays are summarised.

Most RNN applications are still using first-order learning algorithms despite the drawbacks of the GD. Some attempts have been made to propose second-order learning algorithms, e.g. dos Santos & von Zuben (2000) proposed a quasi 2nd-order method. Also, simulated annealing has given some promising results but the training time is relatively higher (Bengio et al., 1994).

Table 2 provides an overview of RNNs learning, giving examples of training algorithms for locally and globally RNNs for various applications.

FUTURE TRENDS

Recent directions in RNN research focus on investigating and proposing new ways for better modelling of non-stationarity in sequences, such as sequences produced when modelling speech or handwritten characters, with no temporal independence assumptions.

With regards to architectures, hybrid models based on combinations of Hidden Markov Models and RNNs as well as modular structures are considered promising approaches to solve sequence processing problems that occur in natural language and speech processing. In addition, a number of applications of the so-called Long Short-Term Memory RNN (Hochreiter & Schmidhuber, 1997) have provided some encouraging

¹ This can be due to sensitivity to initial conditions and the multitudes of local minima

² For example sequences in the area of natural language processing

results, demonstrating that these recurrent architectures can overcome several of the fundamental problems of traditional RNNs, and efficiently learn to solve many previously unlearnable tasks.

As far as RNN training is concerned and despite the popularity of gradient descent approaches, which enforce the monotone decrease of the learning error, there are new learning algorithms that are based on evolutionary algorithms (Schmidhuber et al., 2007) and nonmonotone learning strategies (Peng and Magoulas, 2007) that have shown potential for effective RNN training.

CONCLUSION

Recurrent networks constitute an elegant way of increasing the capacity of feedforward networks to deal with complex data in the form of sequences of patterns. Recurrent neural networks are well known for their power to model temporal dependencies and process sequences for classification, recognition, and transduction. Modern RNNs architectures are capable of learning to solve many previously unlearnable tasks, even in partially observable environments. In this article, we presented several RNN models. We identified the main challenges involved in training RNNs and discussed several algorithmic approaches for training RNN for sequence processing. Lastly, we presented some future directions for work in this area.

KEY TERMS

Artificial Neural Network: A network of many simple processors, called “units” or “neurons”, which provides a simplified model of a biological neural network. The neurons are connected by links that carry numeric values corresponding to weightings and are usually organised in layers. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Backpropagation through Time: An algorithm for recurrent neural networks that uses the gradient descent method. It attempts to train a recurrent neural network by unfolding it into a multilayer feedforward network that grows by one layer for each time step, also called unfolding of time.

Extended Kalman Filter: An online learning algorithm for determining the weights in a recurrent network given target outputs as it runs. It is based on the idea of Kalman filtering, which is a well-known linear recursive technique for estimating the state vector of a linear system from a set of noisy measurements.

Gradient Descent: A popular training algorithm that minimises the total squared error of the output computer by a neural network. To find a local minimum of the error function using gradient descent, one takes steps proportional to the negative of the gradient (or the approximate gradient) of the function at the current point.

Neural Architecture: Particular organisation of artificial neurons and connections between them in an artificial neural network.

Real-Time Recurrent Learning: A general approach to training an arbitrary recurrent network by adjusting weights along the error gradient. This algorithm usually requires very low learning rates because of the inherent correlations between successive node outputs.

Recurrent Neural Network: An artificial neural network with feedback connections. This is in contrast to what happens in a feedforward neural network, where the signal simply passes from the input neurons, through the hidden neurons, to the outputs nodes

Sequence Processing: A sequence is an ordered list of objects, events or data items. Processing of a sequence may involve one or a number of operations, such as classification of the whole sequence into a category; transformation of a sequence into another one; prediction or continuation of a sequence; generation of an output sequence from a single input.

Training Algorithm: A step-by-step procedure for adjusting the connection weights of an artificial neural network. In supervised training, the desired (correct) output for each input vector of a training set is presented to the network, and many iterations through the training data may be required to adjust the weights. In unsupervised training, the weights are adjusted without specifying the correct output for any of the input vectors.

Shortening Automated Negotiation Threads via Neural Nets

INTRODUCTION

In the artificial intelligence domain, an emerging research field that rapidly gains momentum is *Automated Negotiations* (Fatima, Wooldridge, & Jennings, 2007) (Buttner, 2006). In this framework, building intelligent agents (Silva, Romão, Deugo, & da Silva, 2001) adequate for participating in negotiations and acting autonomously on behalf of their owners is a very challenging research topic (Saha, 2006) (Jennings, Faratin, Lomuscio, Parsons, Sierra, & Wooldridge, 2001). In automated negotiations, three main items need to be specified (Faratin, Sierra, & Jennings, 1998) (Rosen-schein, & Zlotkin, 1994): (i) the negotiation protocol & model, (ii) the negotiation issues, and (iii) the negotiation strategies that the agents will employ.

According to (Walton, & Krabbe, 1995), “*Negotiation is a form of interaction in which a group of agents, with conflicting interests and a desire to cooperate try to come to a mutually acceptable agreement on the division of scarce resources*”. These resources do not only refer to money, but also include other parameters, over which the agents’ owners are willing to negotiate, such as product quality features, delivery conditions, guarantee, etc. (Maes, Guttman, & Moukas, 1999) (Sierra, 2004). In this framework, agents operate following predefined rules and procedures specified by the employed negotiation protocol (Rosen-schein, & Zlotkin, 1994), aiming to address the requirements of their human or corporate owners as much as possible. Furthermore, the negotiating agents use a reasoning model based on which their responses to their opponent’s offers are formulated (Muller, 1996). This policy is widely known as the negotiation strategy of the agent (Li, Su, & Lam, 2006).

This paper elaborates on the design of negotiation strategies for autonomous agents. The proposed strategies are applicable in cases where the agents have strict deadlines and they negotiate with a single party over the value of a single parameter (*single-issue bilateral negotiations*). Learning techniques based on MLP and GR Neural Networks (NNs) are employed by the client agents, in order to predict their opponents’ behaviour and achieve a timely detection of unsuccessful negotiations. The proposed NN-assisted strategies have been evaluated and turn out to be highly effective with regards to the duration reduction of the negotiation threads that cannot lead to agreements.

The rest of the paper is structured as follows. In the second section, the basic principles of the designed negotiation framework are presented, while the formal problem statement is provided. The third section elaborates on the NN-assisted strategies designed and provides the configuration details of the NNs employed. The fourth section presents the experiments conducted, while the fifth section summarizes and evaluates the results of these experiments. Finally, in the last section, conclusions are drawn and future research plans are exposed.

THE AUTOMATED NEGOTIATION FRAMEWORK BASICS

This paper studies a single issue, bilateral automated negotiation framework. Thus, there are two negotiating parties (Client and Provider) that are represented by mobile intelligent agents. The agents negotiate over a single issue based on an alternating offers protocol

(Kraus, 2001) aiming to maximize the utilities of the parties they represent.

We hereafter consider the case where the negotiation process is initiated by the Client Agent (CA) that sends to the Provider Agent (PA) an initial Request for Proposal (RFP) specifying the features of the service/product its owner is interested to obtain. Without loss of generality, it is assumed that the issue under negotiation is the price of the product or service. Thus, the PA negotiates aiming to agree on the maximum possible price, while the CA aims to reduce the agreement price as much as possible. Once the PA receives the RFP of the CA, it either accepts to be engaged in the specific negotiation thread and formulates an initial price offer, or rejects the RFP and terminates the negotiation without a proposal. At each round, the PA sends to the CA a price offer, which is subsequently evaluated by the CA against its constraints and reservation values. Then, the CA generates a counter-offer and sends it to the PA that evaluates it and sends another counter-offer to the CA. This process continues until a mutually acceptable offer is proposed by one of the negotiators, or one of the agents withdraws from the negotiation (e.g. in case its time deadline is reached without an agreement being in place). Thus, at each negotiation round, the agents may: (i) accept the previous offer, if their constraints are addressed, (ii) generate a counter-offer, or (iii) withdraw from the negotiation.

Quantity p_l^a denotes the price offer proposed by negotiating agent a during negotiation round l . A price proposal p_l^b is always rejected by agent a if $p_l^b \notin [p_m^a, p_M^a]$, where $[p_m^a, p_M^a]$ denotes agent- a 's acceptable price interval. In case an agreement is reached, we call the negotiation successful, while in case one of the negotiating parties quits, it is called unsuccessful. In any other case, we say that the negotiation thread is active. The objective of our problem is to predict the PA's behaviour in the future negotiation rounds until the CA's deadline expires. More specifically, the negotiation problem studied can formally be stated as follows:

Given: (i) two negotiating parties: a Provider that offers a specific good and a Client that is interested in this good's acquisition, (ii) the acceptable price interval $[p_m^C, p_M^C]$ for the Client, (iii) a deadline T_C up to which the Client must have completed the negotiation with the Provider, (iv) the final negotiation round index L_C for the Client, (v) a round threshold L_C^d until which the Client must decide whether to continue be-

ing engaged in the negotiation thread or not, and (vi) the vector $P_l^P = \{p_l^P\}$, where $l = 2k - 1$ and $k = 1, \dots, \lfloor \frac{L_C^d}{2} \rfloor$, of the prices that were proposed by the Provider during the initial $L_C^d - 1$ negotiation rounds, *find* (i) the vector $P_{l'}^P = \{p_{l'}^P\}$, where $l' = 2k' - 1$ and $k' = \lfloor \frac{L_C^d}{2} \rfloor + 1, \dots, L_C$, of the prices that will be proposed by the Provider during the last $L_C - L_C^d$ rounds, and (ii) decide on whether the Client should continue being engaged in the specific negotiation thread or not.

A NEGOTIATION STRATEGY BASED ON NEURAL NETWORKS

The policy employed by negotiating agents in order to generate a new offer is called *negotiation strategy*. In principle, three main families of automated negotiation strategies can be distinguished: time-dependent, resource-dependent and behaviour-dependent strategies (Faratin, Sierra, & Jennings, 1998). These strategies are well defined functions that may use various input parameters in order to produce the value of the issue under negotiation to be proposed at the current negotiation round. The proposed mechanism enhances any of the legacy strategies with learning techniques based on Neural Networks (NNs). In the studied framework, the NN-assisted strategies are used by the CA in order to estimate the future behaviour of the PA. This section presents the proposed NN-assisted strategy and describes the specifics of the NNs employed.

Enabling PA Behaviour Prediction

As already mentioned, the research presented in this paper aims to estimate the parameters governing the PA's strategy enabling the CA to predict the PA's future price offers. The objective is to decide at an early round whether to aim for an agreement with the specific PA, or withdraw from the negotiation thread as early as possible, if no agreement is achievable. For this purpose, two different Neural Networks (NNs) have been employed. These NNs are trained off-line with proper training sets and are then used during the on-line negotiation procedure whenever the CA requires so. The procedure starts normally, and as long as there are enough proposals made by the PA, the CA uses the NNs to make a reliable prediction of its opponent's strategy. This requires only a few negotiation rounds (compared to the CA's deadline expiration round) and

this is the main reason why this technique turns out to be significantly useful.

In addition to the $[p_m^a, p_M^a]$ interval, there are mainly 3 other parameters that determine the agent's negotiation strategy: parameter $k^a \in [0,1]$ that determines the initial offer made by the agent at $t = 0$, the concession rate $\beta > 0$ (Faratin, Sierra, & Jennings, 1998), and the PA's last round L_p . In this paper, k^a does not lie among the parameters for prediction as it is safely assumed that the PA initiates the procedure from its maximum price offer. Without loss of generality, we focus on the case where the PA follows a polynomial strategy of arbitrary concession rate and timeout.

The CA negotiates based on a legacy strategy until round L_C^d . Then, the CA makes use of the NNs to obtain estimations β and L_p . Round L_C^d will be hereafter called the *prediction round*. In the experiments conducted we have $L_C^d = 30$ and $L_C = 100$. Based on the history of the PA's price offers, NNs attempt to produce a valid estimation of the PA's offer generation function. Then, the CA may determine whether the current negotiation thread can lead to an agreement or this is not feasible given the CA's deadline. Thus, the NN-assisted strategy enables the CA to save time and withdraw early from negotiation threads that will end unsuccessfully.

The Neural Networks Employed

In our framework, where the prediction of a continuous function is required, we selected to study two types of NNs having no feedback loops: the multilayer perceptron (MLP) NN and the Generalized Regression (GR) NN. The latter is a special case of a Radial Basis Function (RBF) NN that is more appropriate for on-line function approximation (Haykin, 1999). Both networks were selected because of their suitability in such kinds of problems (Haykin, 1999).

For the MLP, we used a training function based on the Levenberg-Marquardt algorithm (Hagan, Demuth, & Beale, 1996) as it is the most convenient for such problems. The network was properly trained over 190 different input vectors (200 epochs each) representing a different combination of PA's offers based on a specific strategy. The best MLP architecture was decided after extensive experiments and set to 23 (log-sigmoid) – 3 (linear) neurons, for the hidden and the output layer respectively. Similarly, the GR network was trained over 280 different vectors to achieve accurate performance characteristics resulting in a 280 (hidden RBF neurons) – 3 (output) architecture.

Both NNs are employed by CAs and can provide reliable prediction of the PA's behaviour, once sufficient input samples (proposals) are available. The experiments conducted and the NNs performance evaluation, are presented in the two following sections.

EXPERIMENTS

In this section, the experiments conducted to evaluate the performance of the designed MLP and the GR NNs concerning the estimation of the future behaviour of the negotiating PA are presented. The first experiments' family aims to compare the actual behaviour of the PA with the one predicted by the MLP and the GR NNs, when $[p_m^p, p_M^p] = [0,100]$, $L_p = 200$ and $\beta \in [0.1, 10]$. The sample values for β are derived from a uniformly distributed random vector of 100 values in the aforementioned area: 50 $\beta < 1$ (Boulware) and 50 $\beta > 1$ (Conceder). The estimated parameters include: the future PA offers until the 100th negotiation round, the minimum PA price offer until then and the PA's concession rate (β). The second experiment family investigates the case where $[p_m^p, p_M^p] = [0,100]$, $\beta = 1$ and $L_p \in [150, 250]$. The sample values for L_p are: 150:1:250. The estimated parameters include: the future PA price offers until the 100th negotiation round and the minimum PA price offer until then.

As illustrated in Figure 1, where the first experiment set is depicted, the MLP- and the GR-NN perform very similarly, managing to accurately predict the PA's price offer in general. In the same Figure, one may observe that both NNs are used until $\beta \leq 2.8$. For higher concession rates and for polynomial PA strategies, an agreement is reached before the 30th round and the NN is not necessary for opponent behaviour prediction. As depicted in Figure 2, where the NNs are tested over linear PA's strategy, the MLP- and the GR-NN perform almost identically estimating the PA's price offer with low error margin. However, the deviation between the actual and the estimated PA offers increases as the round index increases and the PA timeout decreases. This is due to the fact that both NNs have a tendency to slightly underestimate PA's concession rate, especially when $\beta \geq 0.5$. This is confirmed by Figure 3a, where the MLP-NN and the GR-NN estimations of the concession rate are depicted along with the actual β of the PA, over the entire set of conducted experiments. Finally, as depicted in Figure 3b, with regards to the

Figure 1. Actual PA price offer and PA price offer predicted by (a) a MLP-NN and (b) a GR-NN, for 100 negotiation rounds when $L_p = 200$, $p_m^P = 0$, $p_M^P = 100$ and $\beta \in [0.1, 10]$

Figure 2. Actual PA price offer and PA price offer predicted by (a) an MLP-NN and (b) a GR-NN, for 100 negotiation rounds when $\beta = 1$, $p_m^P = 0$, $p_M^P = 100$ and $L_p \in [150, 250]$

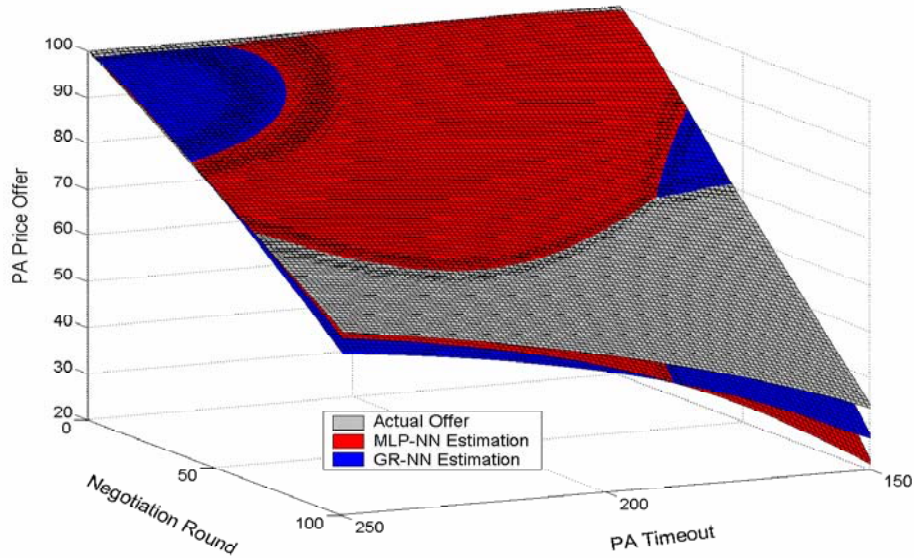

Figure 3. (a) Actual and estimated (by MLP and GR NNs) concession rate values when $L_p = 200$, $p_m^P = 0$, $p_M^P = 100$ and $\beta \in [0.1, 10]$. (b) Actual and estimated (by MLP and GR NNs) PA minimum price offer for all the experiments conducted in both families.

estimation of the PA's minimum price offer, the MLP slightly outperforms the GR. A brief analysis of all these findings is presented in the subsequent section.

EVALUATION

In Table 1 comparative results for two experiment families are illustrated with regards to the mean estimation errors of the MLP and the GR NNs concerning the PA price offer, the PA minimum price offer and the PA's concession rate. For all experiment families we have $[p_m^P, p_M^P] = [0, 100]$. The rest of the parameter settings are presented in the table's first column, while at the second column the number of the experiments where the NN estimation was used is depicted. The results presented in the rest of the table indicate that the MLP NN slightly outperforms the GR NN with regards to the PA (minimum) price offer estimation demonstrating 0.5% - 2.4% higher accuracy in average. However, the opposite stands concerning the PA beta estimation, as the GR NN provides more accurate estimations by more than 3% in average.

In Table 2, evaluation results for the two NN-assisted negotiation strategies are illustrated for both experiment families assuming that $p_M^C = 50^1$. These results include the number unsuccessful negotiation threads (UNTs) (that are due to the fact that $p_m^P > p_M^C$

) and the duration of the UNTs ($L_c = 100^2$) in case no opponent behaviour prediction mechanism is used, the number of UNTs detected by the NNs at round 30, the UNTs that were detected and thus terminated early by the NNs, the mean duration of the UNTs and the mean UNT duration decrease. These results indicate that the MLP and the GR NNs manage to identify ~91% and ~83% of the UNTs in average, respectively. Furthermore, the MLP and the GR NNs achieve ~64% and ~58% reduction of the UNTs' duration in average, respectively. With regards to the elimination of the UNTs, the MLP-assisted strategy clearly outperforms the GR-assisted negotiation strategy. For the reasons above, it is estimated that MLP NNs are more appropriate for assisting negotiating intelligent agents to predict their opponent's behaviour at an early negotiation round in case the agent values a timely detection of unsuccessful negotiation threads.

CONCLUSION

This paper proposed to use Neural Networks in order to enhance negotiating agents with learning techniques enabling them to predict their opponents' negotiation behaviour. The designed NN-assisted negotiation strategy turns out to be very useful, as it leads to substantial duration reduction of unsuccessful negotiation threads,

Table 1. Comparative results concerning the mean estimation error of the two NN-assisted negotiation strategies for the PA price offers, for the PA min offer and the PA concession rate.

| Experiment Settings | Times NN-estimation was used | Mean [price-offer estimation error] | | Mean [min-price-offer estim. error] | | Mean [beta estimation error] | |
|----------------------------------|------------------------------|-------------------------------------|-------|-------------------------------------|-------|------------------------------|--------|
| | | MLP | GR | MLP | GR | MLP | GR |
| $\beta \in [0.1, 10], L_p = 200$ | 4118 | 0.97% | 2.12% | 0.41% | 2.80% | 15.65% | 8.26% |
| $L_p \in [150, 250], \beta = 1$ | 7171 | 1.21% | 1.71% | 8.26% | 8.91% | 12.51% | 12.73% |
| OVERALL | 11289 | 1.12% | 1.86% | 5.40% | 6.68% | 13.92% | 10.72% |

Table 2. Comparative results concerning the unsuccessful negotiation thread detection by the two NN-assisted negotiation strategies

| Experiment Settings | # Unsuc. Negot. Threads (UNTs) | Mean duration of UNTs (no NN) | # UNTs detected at round 30 | | UNTs' elimination ratio | | Mean UNTs' duration | | Mean UNTs' duration decrease | |
|--|--------------------------------|-------------------------------|-----------------------------|----|-------------------------|-------|---------------------|------|------------------------------|-------|
| | | | MLP | GR | MLP | GR | MLP | GR | MLP | GR |
| $\beta \in [0.1, 10], L_p = 200, p_M^c = 50$ | 50 | 100 | 49 | 49 | 98.0% | 98.0% | 31.4 | 31.4 | 68.6% | 68.6% |
| $L_p \in [150, 250], \beta = 1, p_M^c = 50$ | 51 | 100 | 43 | 35 | 84.3% | 68.6% | 41.0 | 52.0 | 59.0% | 48.0% |
| OVERALL | 101 | 100 | 92 | 84 | 91.1% | 83.2% | 36.2 | 41.8 | 63.8% | 58.2% |

due to the fact that the cases where agreements are not achievable are detected at an early stage. Thus, the NNs support the decision of the agents to withdraw or not from the ongoing negotiation threads. More specifically, when the CA uses the NN-assisted strategies it is capable of predicting its opponent's behaviour with significant accuracy, thus getting aware of the potential outcome of the negotiation. Both the MLP and the GR NNs studied demonstrate average opponent price offer estimation error lower than 2% and PA min acceptable price estimation error $\sim 6\%$. Additionally, the unsuccessful negotiations are detected by the MLP NN in more than 90% of the cases in average, demonstrating $\sim 8\%$ better overall performance than the GR NN. Thus, the MLP NN is proven to be more appropriate, when the CA aims to avoid a possible unprofitable or even unachievable agreement. This leads to minimization of the required time and processing resources and to maximization of the CAs overall profit from a series of threads for a single commodity.

KEY TERMS

Automated Negotiation: It is the process by which group of actors communicate with one another aiming to reach to a mutually acceptable agreement on some matter, where at least one of the actors is an autonomous software agent.

Bilateral Negotiation: A negotiation procedure, where exactly two parties are involved, i.e. a client and a provider.

Backpropagation Algorithm: A supervised learning technique used for training artificial NNs based on the minimisation of the error obtained from the comparison between the desired output and the actual one when applying specific inputs.

Generalized-Regression (GR) NN: A GR NN is a special case of a RBF NN with a second linear layer and is often used for function approximation.

Multi-Layer Perceptron (MLP): A fully connected feedforward NN with at least one hidden layer that is trained using back-propagation algorithmic techniques.

Negotiation Protocol: The set of rules that govern the interactions between the negotiating parties.

Negotiation Strategy: The reasoning model based on which the negotiating parties formulate their response to their opponent's offers.

Neural Network (NN): A network modelled after the neurons in a biological nervous system with multiple synapses and layers. It is designed as an interconnected system of processing elements organized in a layered parallel architecture. These elements are called neurons and have a limited number of inputs and outputs. NNs can be trained to find nonlinear relationships in data, enabling specific input sets to lead to given target outputs.

Radial Basis Function (RBF): Function that involves a distance criterion with respect to a centre, such as a circle, ellipse or Gaussian.

RBF NN: It is an artificial NN, the activation functions of which are radial basis functions. It has two layers of processing, where the first maps the input onto each RBF neuron in the other (hidden) layer.

ENDNOTES

- ¹ We selected the p_M^C to be equal to the median value in the PA's acceptable price interval.
- ² To be more accurate, the duration of UNTs is equal to: $\min(L_C, L_p)$. However, in this paper's study, we always have $L_C < L_p$, and thus the duration of UNTs is equal to L_C .

Signed Formulae as a New Update Process

INTRODUCTION

The **agent** paradigm has recently increased its influence in the research and development of computational logic-based systems. A clear and correct specification is made through Logic Programming (LP) and **Non-monotonic Reasoning** that have been brought (back) to the spotlight. Also, the recent significant improvements in the efficiency of **LP** implementations for Non-monotonic Reasoning (De Schreye, Hermenegildo & Pereira, 1999) have helped to this resurgence. However, the agents need update constantly their knowledge base and, particularly the intentional base (rules) such that our agent has the ability to reacting to changes in dynamic environments is of crucial importance within the context of software agents. Such feature should correspond to a deliberative rational behavior wanted for our agents.

The quality of the service that an agent offers is based on the form in which an agent combines rationality and reactivity. A reactive agent can offer well evaluated recommendations but, this response is based on outdated information, while a rational behavior may generate recommendations based on the most recently acquired information. So, we are interested in developing environment-aware agents. For this reason, is very important to have an update process for agents, i.e., that it allows us to design agents with its rational component.

Over recent years, several semantics for logic program **updates** have been proposed (Brewka, Dix, & Knödlige 1997) (De Schreye, Hermenegildo, & Pereira, 1999) (Katsumo & Mendelzon, 1991). All

these semantic ones coincide in considering the AGM proposal as the standard model in the update theory, for their wealth in **properties**. The AGM approach, introduced in (Alchourron, Gardenfors & Makinson, 1985) is the dominating paradigm in the area, but in the context of monotonic logic. All these proposals analyze and reinterpret the AGM postulates under the **Answer Set Programming** (ASP) such as (Eiter, Fink, Sabattini & Thompits, 2000). However, the majority of the adapted AGM and update postulates are violated by update programs, as shown in (De Schreye, Hermenegildo, & Pereira, 1999). For this reason, we have been working in finding properties that our update operator satisfies (Osorio & Zacarías, 2003) (Zacarías & Osorio, 2005) (Arrazola & Zacarias, 2005). Our purpose is to build a semantics based on structural properties. This is our main objective in the **update** theory. In (De Schreye, Hermenegildo, & Pereira, 1999) (Osorio & Zacarias, 2003) (Zacarías, Osorio & Arrazola, 2005) (Zacarias, 2005) the authors present a set of properties that the update operator satisfies. In this paper we continue with this same research line presenting a novel proposal with the aim to enrich the **update theory** that we have begun in (Osorio & Zacarias, 2003) (Zacarías, Osorio & Arrazola, 2005) (Zacarias, 2005). This novel proposal contributes with two benefits. First, we conserve many of the properties presented in previous works (Osorio & Zacarias, 2003) (Zacarías, Osorio & Arrazola, 2005) (Zacarias, 2005), such as: Weak Irrelevance of Syntax (WIS). This property is similar to one postulate proposed by AGM, but in this case for **nonmonotonic logic** and under **Answer Set Programming** (ASP) introduced and defined by (Gelfond & Lifschitz, 1988).

BACKGROUND

In this section, we present advances in the updates context. Also, we give some general definitions for our theory. We define our theory about logic programs.

Advances on Updates

We consider the task of updating logic programs under **non-monotonic reasoning** and a purely logical view. Since an intelligent agent is situated in an environment which is subject to change, it is required the agent to be adapted over time. For agents utilizing logic programming techniques for representing their knowledge, it is required the agent to be capable of updating logic programs accordingly, in order to ensure adaptability. We chose one of the approaches; viz. update answer set semantics (Zacarias, 2005) (Osorio & Zacarias, 2003) (Eiter, Fink, Sabattini & Thompits, 2000) (Banti, Alferes & Brogi, 2003). Besides, an underlying update semantics, which specifies how new, possibly inconsistent information, have to be incorporated into the knowledge base, an agent needs to have a certain **update** policy, i.e., a specification of how to react upon the arrival of an update. The issue of how to specify change requests for knowledge bases has received growing attention more recently and suitable specification languages for **non-monotonic logic** programs have been developed (Leite, 2001) (Leite, 2002).

In (Zacarias, 2005) we have introduced a new proposal towards the enrichment of the update operator “ \oplus ”. There, we have presented a refinement of the **stable model** semantics for the update operator. Also, we presented a new property that allows us to face updates where new information contains rules that define a conservative extension. So, we gave an extension of our properties proven in (Osorio & Zacarias, 2003), under N logic. This approach is based on the work made by Eiter et al. (Eiter, Fink, Sabattini & Thompits, 2000), and inspired in a recent approach presented by Alferes et al. (Banti, Alferes & Brogi, 2003). With this work, we improve and enrich the update operator proposed by Eiter et al. (Eiter, Fink, Sabattini & Thompits, 2000), giving as result a new update operator.

UPDATES FOR REAL TIME APPLICATIONS

In this section we present a novel mechanism that allows updating a knowledge base in a quick and easy way. Furthermore, this proposal satisfies similar structural properties to those that we have presented in previous works. So, we give the basic concepts for our theory and we present our main contribution based on **signed formulae** (Ariely, Denecker, Nuffelen & Bruynooghe, 2004).

Preliminary

Rules are built from propositional atoms and the 0-place connectives \top and \perp using negation as failure (\neg) and conjunction (\wedge). A *rule* is an expression of the form:

$$\text{Head} \leftarrow \text{Body} \quad (1)$$

If Body is \top then we identify rule (1) with rule Head. If a Head is \perp then we identify rule (1) with a restriction. A *program* is a set of rules. A logic program P is a (possibly infinite) set of rules. For a program P , I is a model of P , denoted $I \models P$, if $I \models L$ for all $L \in P$. As it is shown in (Brewka, Dix, & Knollige, 1997), the Gelfond-Lifschitz transformation for a program P and a model $N \subseteq B_p$ (B_p denotes a set of atoms that appear in P) is defined by

$$P^N = \{rule^N : rule \in P\}$$

where $(A \leftarrow B_1, \dots, B_m, \neg C_1, \dots, \neg C_n)^N$ is either:

- a. $A \leftarrow B_1, \dots, B_m$, if $\forall j \leq n: C_j \notin N$;
- b. \top ,

otherwise

Note that P^N is always a definite program. We can therefore compute its least Herbrand model (denoted as M_{P^N}) and check whether it coincides with the model N which we started with:

Definition 1. (Gelfond & Lifschitz, 1988) N is a **stable model** of P iff N is the minimal model of P^N

DATABASE REPAIRS

In this document we present our more recent approach about update under repairs to database. The way in that we approach the update problem is based on (Ariely, Denecker, Nuffelen & Bruynooghe, 2004), i.e., based on the idea of **repair inconsistent database**. So, given a possibly inconsistent database this mechanism represents the possible ways to restore its consistency in terms of **signed formulae**. In our context, this mechanism is used to incorporate new information that can be inconsistent with the previous database containing the **agent's knowledge**.

In a similar form as in (Ariely, Denecker, Nuffelen & Bruynooghe, 2004), L defines a first order language, S is a fixed database schema and D a fixed domain. A database instance D consists of atoms in the language L , where D has a finite active domain, $A(D)$, which is a subset of D .

Definition 2. (Ariely, Denecker, Nuffelen & Bruynooghe, 2004) a database is a pair (D, IC) , where D is a database instance, and IC , the set of integrity constraints, is a finite and classically consistent set of formulae in L .

So, a database is (Ariely, Denecker, Nuffelen & Bruynooghe, 2004): $DB = (D, IC)$, let

$$DB^A = D \cup ICA = D \cup \{\rho(\psi) \mid \psi \in IC, \rho : \text{var}(\psi) \rightarrow A(D)\}$$

Where ρ is a ground substitution of variables to the individuals of $A(D)$, the active domain of D , DB is called the Herbrand expansion of DB . As D , IC and $A(D)$ are all finite sets, DB^A is also finite, and so $\Sigma^{DB} = \{p_1, p_2, \dots, p_n\}$, the set of the atomic formulae that appear in DB^A , is finite as well.

UPDATES BASED ON SIGNED FORMULAE

For their simplicity our new **update** process is suitable for applications that have to give answers in real time. In (Ariely, Denecker, Nuffelen & Bruynooghe, 2004) the authors suppose that the database is inconsistent, and then they give a general description of how to restore the consistency of databases instances that do not satisfy

a given set of integrity constraints. Here, we adapt this method to updates of logic programs and we illustrate that this can be used efficiently in our context.

Here, we consider updates in the setting of logic programs, i.e., we consider that a database is represented by a logic program. So, in our context, we start with the fact that our database is updated with new information that it causes an **inconsistent database**. At this moment, we apply this method with the objective of making our database consistent. Follow, we present a general framework used in (Ariely, Denecker, Nuffelen & Bruynooghe, 2004). A database is a pair (D, IC) , where D is a database instance, and IC , the set of integrity constraints, is a finite and classically consistent set of formulae in a language.

Given a possibly inconsistent database, our goal is to restore its consistency, i.e., to repair the database:

Definition 3. Similarly as in (Ariely, Denecker, Nuffelen & Bruynooghe, 2004) an update of a database $DB = (D, IC)$ is a pair $\{\text{Insert}, \text{Retract}\}$, s.t. $\text{Insert} \cap D = \emptyset$ and $\text{Retract} \subseteq D$. A pair of DB is an update of DB, for which $(D \cup \text{Insert} \setminus \text{Retract}, IC)$ is a consistent database.

The intuitive meaning is as follows: a database is **updated** by inserting the elements of **insert** and removing the elements of **Retract**. An update is a pair when the resulting database is consistent. Note that if DB is consistent, then (\emptyset, \emptyset) is a pair of DB.

As follows, we give some examples that illustrate how this mechanism is adapted to updates.

Example 1. This example illustrates a daily update regarding the energy flaw (Eiter, Fink, Sabattini & Thompits, 2000). Suppose that you have the following database:

DB: sleep $\leftarrow \neg \text{tv-on}$.
 night.
 tv-on.
 watch-tv $\leftarrow \text{tv-on}$.
 $\leftarrow \text{power-failure, tv-on}$.

Here, the DB is consistent, however, if we update the DB with the following rule:

power-failure.

This DB is not consistent. Following the format defined in (Ariely, Denecker, Nuffelen & Bruynooghe, 2004) this example is the pair:

$$DB = (\{\text{sleep} \leftarrow \neg \text{tv-on.}, \text{night.}, \text{tv-on.}, \text{watch-tv} \leftarrow \text{tv-on.}, \text{power-failure.}\}, \{\leftarrow \text{power-failure}, \text{tv-on.}\})$$

Therefore, we can adapt the method proposed in (Ariely, Denecker, Nuffelen & Bruynooghe, 2004) and to carry out a correct update of this database as follows:

First, we add our initial configuration the new information (update):

$$DB = (\{\text{sleep} \leftarrow \neg \text{tv-on.}, \text{night.}, \text{tv-on.}, \text{watch-tv} \leftarrow \text{tv-on.}, \text{power-failure.}\}, \{\leftarrow \text{power-failure}, \text{tv-on.}, \text{power-failure.}\})$$

Second, we obtain the **signed formula**:

$$(\neg \text{power-failure} \vee \neg \text{tv-on}) \wedge \text{power-failure.}$$

Using format of (Ariely, Denecker, Nuffelen & Bruynooghe, 2004) we obtain:

$$(\neg \neg S_{\text{power-failure}} \vee \neg \neg S_{\text{tv-on}}) \wedge \neg S_{\text{power-failure}}.$$

it is equivalent to:

$$(S_{\text{power-failure}} \vee S_{\neg \text{tv-on}}) \wedge \neg S_{\text{power-failure}}.$$

Third, we calculate v^R the valuation that is associated with R, obtaining:

$$\begin{aligned} v^R(S_{\text{power-failure}}) &= 1 \\ v^R(S_{\text{tv-on}}) &= 1 \\ v^R(\neg S_{\text{power-failure}}) &= 0 \end{aligned}$$

Therefore, we have: $(\{\text{power-failure}\}, \{\text{tv-on}\})$

This means that the suggested update is:

Insert $\rightarrow \{\text{power-failure}\}$

Retract $\rightarrow \{\text{tv-on}\}$

As we can see, this is the wanted result.

Now, we show another example using the method presented in (Eiter, Fink, Sabattini & Thompits, 2000).

Example 2. This program describes some knowledge about the sky (Banti, Alferes & Brogi, 2003). Suppose that you have the following database:

$$DB: \text{day} \leftarrow \neg \text{night.} \\ \neg \text{see-stars.} \\ \leftarrow \text{see-stars}, \text{day.}$$

Here, the DB is consistent, however, if we update the \$DB\$ with the following rule:

see-stars.

This DB is not consistent. Following the format defined in (Ariely, Denecker, Nuffelen & Bruynooghe, 2004) this example is the pair:

$$DB = (\{\text{day} \leftarrow \neg \text{night.}, \neg \text{see-stars.}\}, \{\leftarrow \text{see-stars}, \text{day.}\})$$

Therefore, we can adapt the method proposed in (Ariely, Denecker, Nuffelen & Bruynooghe, 2004) obtaining a correct update of this database as follows:

First, we add our initial configuration to the new information (update):

$$DB = (\{\text{day} \leftarrow \neg \text{night.}, \neg \text{see-stars.}\}, \{\leftarrow \text{see-stars}, \text{day}, \text{see-stars.}\})$$

Second, we obtain the **signed formula**:

$$(\neg \text{see-stars} \vee \neg \text{day}) \wedge \text{see-stars.}$$

Using format of (Ariely, Denecker, Nuffelen & Bruynooghe, 2004) we obtain:

$$(\neg \neg S_{\text{see-stars}} \vee \neg \neg S_{\text{day}}) \wedge \neg \neg S_{\text{see-stars}}.$$

it is equivalent to:

$$(S_{\text{see-stars}} \vee S_{\text{day}}) \wedge S_{\text{see-stars}}.$$

Third, we calculate v^R the valuation that is associated with R, obtaining:

$$\begin{aligned} v^R(S_{\text{see-stars}}) &= 1 \\ v^R(S_{\text{day}}) &= 1 \\ v^R(S_{\neg \text{see-stars}}) &= 0 \end{aligned}$$

Therefore, we have: ($\{\text{see-stars}\}$, $\{\text{day}\}$)

This means that the suggested update is:

Insert $\rightarrow \{\text{see-stars}\}$

Retract $\rightarrow \{\text{day}\}$ this is, as desired.

FUTURE TRENDS

Just as in (Eiter, Fink, Sabattini & Thompits, 2000) we coincide that because of apparent lack of minimality of change, we then considered refinements of the semantics in terms of minimal and strictly minimal answer sets. Several issues remain for further work. An interesting point (Eiter, Fink, Sabattini & Thompits, 2000) concerns the formulation of postulates (principles or properties) for update operator on logic programs and, more generally, on **non-monotonic theories**. As you can see in (Eiter, Fink, Sabattini & Thompits, 2000), several postulates from the area of logical theory change fail for update programs. This may be explained by the dominant role of syntax for update embodied by causal rejection of rules.

We have extended our operator to Pstable semantics. However, we should continue working in this line, since there are properties such as the following:

$$P \oplus P_1 \oplus Q \equiv P \oplus P_2 \oplus Q$$

for every program P_i and Q , that are not always satisfied, due to our property is just satisfied by the right.

We consider that the future researches rotated around the search of properties that the update operator satisfies, and that in principle they have been begun by some authors (Osorio & Zacarias, 2003) (Banti, Alferes & Brogi, 2003) (Eiter, Fink, Sabattini & Thompits, 2000) (Zacarias, Osorio & Arrazola, 2005) (Zacarias, 2005).

CONCLUSION

In this paper, we considered a new proposal to provide an update process to our agents. Our proposal is a novel and simple methodology that allows an agent to maintain updated its knowledge base in all moment. This provides an agent to behave in a rational way, similar to human behavior. Furthermore, it is an appropriate proposal for applications that require answers in real

time. Also, this proposal opens the possibilities for building real-life applications, like intelligent agents whose rational component is modelled by a knowledge base, which is in turn maintained using **update logic programs**.

KEY TERMS

Beliefs: An agent whose knowledge base is the theory T believes F if and only if F belongs to every intuitionistically complete and consistent extension of T by adding only negated literals.

Equivalence: Two programs are *equivalent* if they have exactly the same answer sets.

Intelligent Agent: An intelligent agent is a component of software (or hardware) that it perceives and it acts autonomously in an open and dynamic environment, learning and cooperating with other agents (the same user) to offer a benefit to their user.

Principle of Irrelevance of Syntax: The meaning of the knowledge that results from an update must be independent of the syntax of the original knowledge, as well as independent of the syntax of the update itself.

Strong Equivalence: (Lifschitz, Pearce & Valverde, 2001). We say that P_1 and P_2 are *strongly equivalent* if for every program P , $P_1 \cup P$ and $P_2 \cup P$ have the same answer sets.

Update: Let P be the program representing the current knowledge base, if it is updated by another

program U , then P_U is a program updated of P if only if the models of P_U are the result of updating each of the models of P according to a given semantics S ; to each of these models apply the update request U to obtain a new set of models M ; P_U is any logic program whose models are exactly M .

Weak Irrelevance of Syntax: $T_1 \equiv T_2$ implies $Bel(K \nabla T_1) = Bel(K \nabla T_2)$, where K , T_1 and T_2 are any theories, $Bel(T)$ defines the set of answer sets of T , ∇ is the update operator, and understanding that equivalence means that both programs (T_1 and T_2) have the same answer sets.

Solar Radiation Forecasting Model

INTRODUCTION

The prediction of hourly solar radiation data has important consequences in many solar applications (Markvart, Fragaki & Ross, 2006). Such data can be regarded as a time series and its prediction depends on accurate modeling of the stochastic process. The computation of the conditional expectation, which is in general non-linear, requires the knowledge of the high order distribution of the samples. Using a finite data, such distributions can only be estimated or fit into a pre-set stochastic model. Methods like Auto-Regressive (AR) prediction, Fourier Analysis (Dorvlo, 2000) Markov chains (Jain & Lungu, 2002) (Muselli, Poggi, Notton & Louche, 2001) and ARMA model (Mellit, Benghanem, Hadj Arab, & Guessoum, 2005) for designing the non-linear signal predictors are examples to this approach. The neural network (NN) approach also provides a good to the problem by utilizing the inherent adaptive nature (Elminir, Azzam, Younes, 2007). Since NNs can be trained to predict results from examples, they are able to deal with non-linear problems. Once the training is complete, the predictor can be set to a fixed value for further prediction at high speed. A number of researchers have worked on prediction of global solar radiation data (Kaplanis, 2006) (Bulut & Buyukalaca, 2007). In these works, the data is treated in its raw form as a 1-D time series, therefore the inter-day dependencies are not exploited. This article introduces a new and simple approach for hourly solar radiation forecasting. First, the data are rendered in a matrix to form a 2-D image-like model. As a first attempt to test the 2-D model efficiency, optimal linear image prediction filters (Gonzalez, 2002) are constructed. In order to take into account the adaptive nature for complex and non-stationary time series, NNs are also applied to the forecasting problem and results are discussed.

BACKGROUND

This article presents a two-dimensional model approach for the prediction of hourly solar radiation. Before proceeding with the prediction results, the following technical background is provided. Using the described tools, the approach is tested with optimal coefficient linear filters and artificial NNs (Hocaoglu, Gerek & Kurban, 2007).

The 2-D Representation of Solar Radiation Data

The collected hourly solar radiation data is a 1-D discrete-time signal. In this work, we render this data in a 2-D matrix form as given in equation 1.

$$Rad = \begin{pmatrix} x_{11} & \cdots & x_{1n} \\ \vdots & \ddots & \vdots \\ x_{m1} & \cdots & x_{mn} \end{pmatrix} \quad (1)$$

where the rows and columns of the hourly solar radiation matrix indicate days and hours, respectively. Such 2-D representation provides significant insight about the radiation pattern with time. First surface plot of the data is obtained then image view of the data is obtained and given in Fig 1.

By inspecting the image version of the data in Fig. 1, it is easy to interpret daily and seasonal behavior of solar radiation. Dark regions of the image indicate that there is no sun shine on horizontal surface. The transition from black to white indicates that solar radiation fall on horizontal surface is increasing or decreasing. During winter time, the dawn to dusk period is shorter, producing a narrower protruding blob. Conversely, the

Figure 1. Image view of solar radiation data

white blob is wider during summer times, indicating that the day-time is longer. The width behavior of the white blob clearly indicates the seasonal changes of sun-light periods. The horizontal *and* vertical correlations within the 2-D data are quite pronounced. This implies that, given the vertical correlation among the same hours of consecutive days, it is beneficial to use 2-D prediction for hourly forecasting. The prediction efficiency of the proposed model is illustrated with 2-D optimum linear prediction filters and NNs.

Optimal 2-D Linear Prediction Filter Design

Due to predictive image coding literature, it is known that a 2-D matrix can be efficiently modeled by linear predictive filters (Gonzales, 2002) (Sayood, 2000). The prediction domain is a free parameter determined according to the application. Consider a three coefficient prediction filter structure as given in expression 2:

| | |
|-------------|-------------------------|
| C | $x_{i,j+1}$ |
| $x_{i+1,j}$ | $\hat{x}_{i+1,j+1} = ?$ |

(2)

The linear filter coefficients a_1 , a_2 and a_3 are optimized, and the prediction result $\hat{x}_{i+1,j+1}$ is estimated as

$$\hat{x}_{i+1,j+1} = x_{ij} \cdot a_1 + x_{i(j+1)} \cdot a_2 + x_{(i+1)j} \cdot a_3 \quad (3)$$

The prediction error for this term is:

$$\epsilon_{i+1,j+1} = \hat{x}_{i+1,j+1} - x_{i+1,j+1} \quad (4)$$

The total error energy corresponding to the whole image prediction can be calculated as:

$$\epsilon = \sum_{i=2}^m \sum_{j=2}^n \epsilon_{ij}^2 \quad (5)$$

where m and n correspond to the width and height of the image, which are, for the solar data, 365 and 24, respectively. The filter coefficients that minimize this function can be found from the solution of the minimization derivative equation:

$$\frac{\partial \epsilon}{\partial a_1} = \frac{\partial \epsilon}{\partial a_2} = \frac{\partial \epsilon}{\partial a_3} = 0 \quad (6)$$

The solution to equation 6 yields the following matrix-vector equation:

$$\begin{bmatrix} R_{11} & R_{12} & R_{13} \\ R_{21} & R_{22} & R_{23} \\ R_{31} & R_{32} & R_{33} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ a_3 \end{bmatrix} = \begin{bmatrix} r_1 \\ r_2 \\ r_3 \end{bmatrix} \quad (7)$$

which is compactly written as $\mathbf{R} \cdot \mathbf{a} = \mathbf{r}$, so the optimal filter coefficients can be obtained as

$$\mathbf{a} = \mathbf{R}^{-1} \mathbf{r} \quad (8)$$

A Brief Discussion on Learning Techniques of NNs

There are several techniques to achieve high speed NN algorithms. Among these techniques, heuristic techniques were developed from an analysis of the performance of the standard steepest descent algorithm (Costa, Braga, Menezes, 2007). Among the category of fast algorithms, the methods use standard numerical optimization techniques such as conjugate gradient, quasi-Newton, and Levenberg-Marquardt. The basic back propagation algorithm adjusts the weights in the steepest descent direction. It turns out that, although the function decreases most rapidly along the negative of the gradient, this does not necessarily produce the fastest convergence. In the conjugate gradient algorithms a search is performed along conjugate directions, which produces generally faster convergence than steepest descent directions. Newtons method is an alternative to the conjugate gradient methods, which often converges faster. As a drawback, the method is complex and expensive for it's the Hessian matrix calculation in feed forward NNs. The computationally simpler quasi-Newton methods do not require calculation of second derivatives. Similarly, the Levenberg-Marquardt algorithm was also designed to approach second-order training speed without having to compute the Hessian matrix. There are a number of studies on different subjects that points the comparison between training algorithms (Ghaffari, Abdollahi, Khoshayand, Bozchalooi, Dadgar & Tehrani, 2006) (Srinivasulu & Jain, 2006) (Pereda, Lope & Maravall, 2006). Since Levenberg-Marquardt algorithm supplies faster convergence it is adopted and used in this article.

SOLAR RADIATION DATA FORECASTING RESULTS

In order to reduce computational complexity and to focus to the proposition, relatively short 1-D and 2-D prediction filters are used in this work. The filter templates are given in Fig. 2. These templates are also widely used in predictive image and signal coding.

For the minimum RMSE linear prediction, the optimal coefficients are analytically determined by solving Eq. 8. The 2-D image data is fed to the prediction system, and error figures are obtained for each hour. The error figure for 2-D 3-tap optimum filter is given in Fig. 3.

As a second step prediction model, two NN structures are applied to the data. In the first structure, the input is treated as 1-D, and the input network elements are i^{th} , $i+1^{st}$ and $i+2^{nd}$ elements of the data, where the output is the $i+3^{th}$ element for each sample in the data. In the second structure, the proposed 2-D image matrix form is used. The inputs of the networks are i,j^{th} , $i+1,j^{th}$ and $i,j+1^{st}$ elements of the 2-D data matrix and the output is $i+1, j+1^{st}$ element of the data matrix for each i and j . A 2-month period is used for testing.

The sigmoid function and the gradient descent algorithm with Levenberg-Marquardt modification are used during learning process with three neurons at the hidden layer. To accelerate the speed of learning process a momentum term is used and is updated by a fraction of the previous weight update to the current one. After the learning phase, the network is simulated by the remaining image data and error samples are obtained (Fig. 4).

Root Mean Square Error (RMSE) values that are obtained from proposed optimum linear prediction filters and NNs are presented in Table I. The correlation coefficients between actual data values and predicted data values are also tabulated here.

FUTURE TRENDS

2-D representation has potential uses for different meteorological parameters and different models such as surface matching, clustering based classification, etc. Dynamical time varying behavior of the model may also be analyzed. Such analysis can be regarded as future works of this study.

Figure 2. 1-D and 2-D prediction templates used for modeling the image

CONCLUSION

In this work, a novel approach is proposed for hourly solar radiation forecasting. The hourly solar radiation is interpreted and rendered as an 2-D image and its properties are examined. It is observed that two dimensional representations give more insight to the solar pattern than the regular 1-D interpretation. As an illustration, 1-D and 2-D optimal linear prediction filters with 3 coefficients are designed and compared in the sense of RMSE and correlation coefficients. The RMS energy value of the data and the prediction sequence are around 198. After applying the prediction, the RMS value of the prediction error reduces down to 44.33 using 1-D prediction. This value also constitutes the standard deviation of the statistical system. By using 2-D prediction, this value is reduced further to 41.09.

To emphasize the efficiency of the proposed 2-D representation, two feed-forward NN structures, one for 1-D modeling and the other for the 2-D, are built and trained by the same data. The RMSE values are obtained as 42.012 and 38.66 for 1-D and 2-D case, respectively. This observation also justifies the efficiency of the 2-D data representation that exploits inter-day dependencies of the solar radiation pattern. Furthermore, it is clear that the 2-D NN structure provides better prediction than the optimum linear filter.

KEY TERMS

2-D Data Representation: A matrix containing vertical and horizontal indexes can also be considered as a 2-D image. A 2-D representation does not have to correspond to an image acquired by a camera or an imaging device. Here, the representation is used for the compact visualization of the solar data.

Artificial Neural Networks: A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Backpropagation Algorithm: Learning algorithm of ANNs, based on minimising the error obtained from the comparison between the outputs that the network gives after the application of a set of network inputs and the outputs it should give (the desired outputs).

Optimal Coefficient Linear Filters: A linear predictor takes a linear combination of past values in a time series, and assigns this combination as the prediction value. While taking the linear combination, the scales of each past sample should be calculated in a way that the prediction error has minimum amount of energy. Such a set of scales are called optimal coefficients of a linear filter.

Prediction Error : Difference between the actually measured and previously forecasted value of a time-series data. Commonly represented in terms of RMSE.

RMSE : Root-Mean-Squared Error. A quantitative error measure that defines the error between two sets of data as one-by-one differencing, squaring each difference, adding the squared terms, and finally taking the square root.

Solar Radiation: Radiant energy emitted by the sun from a nuclear fusion reaction that creates electromagnetic energy.

Speech-Based Clinical Diagnostic Systems

Jesús Bernardino Alonso Hernández

University of Las Palmas de Gran Canaria, Spain

Patricia Henríquez Rodríguez

University of Las Palmas de Gran Canaria, Spain

INTRODUCTION

It is possible to implement help systems for diagnosis oriented to the evaluation of the **fonator system** using speech signal, by means of techniques based on expert systems. The application of these techniques allows the early detection of alterations in the **fonator system** or the temporary evaluation of patients with certain treatment, to mention some examples. The procedure of measuring the **voice quality** of a speaker from a digital recording consists of quantifying different acoustic characteristics of speech, which makes it possible to compare it with certain reference patterns, identified previously by a “**clinical expert**”.

A speech acoustic quality measurement based on an auditory assessment is very hard to assess as a comparative reference amongst different voices and different human experts carrying out the assessment or evaluation.

In the current bibliography, some attempts have been made to obtain objective measures of speech quality by means of multidimensional clinical measurements based on auditory methods. Well-known examples are: GRBAS scale from Japon (Hirano, M., 1981) and its extension developed and applied in Europe (Dejonckere, P. H. Remacle, M. Fresnel-Elbaz, E. Woisard, V. Crevier-Buchman, L. Millet, B., 1996), a set of perceptual and acoustic characteristics in Sweden (Hammarberg, B. & Gauffin, J., 1995), a set of phonetics characteristics with added information about the excitement of the vocal tract. The aim of these (quality speech measurements) procedures is to obtain an objective measurement from a subjective evaluation.

There exist different works in which objective measurements of speech quality obtained from a recording are proposed (Alonso J. B., 2006), (Boyanov, B & Hadjitodorov, S., 1997), (Hansen, J. H. L., Gavidia-Ceballos, L. & Kaiser, J. F., 1998), (Stefan Hadjitodorov & Petar Mitev, 2002), (Michaelis D.; Frohlich M. & Strube H.

W., 1998), (Boyanov B., Doskov D., Mitev P., Hadjitodorov S. & Teston B., 2000), (Godino-Llorente, J. I.; Aguilera-Navarro, S. & Gomez-Vilda, P., 2000).

In these works a voiced **sustained sound** (usually a vowel) is recorded and then used to compute speech quality measurements. The utilization of a voiced **sustained sound** is due to the fact that during the production of this kind of sound, the speech system uses almost all its mechanisms (glottal flow of constant air, vocal folds vibration in a continuous way, ...), enabling us to detect any anomaly in these mechanisms. In these works different sets of measurements are suggested in order to quantify speech quality objectively. In all these works one important fact is revealed; it is necessary to obtain different measurements of the speech signal in order to compile the different aspects of acoustic characteristics of the speech signal.

BACKGROUND

A **speech recording** gives different characteristics of the speech quality of a speaker. The recorded speech signal can be represented in different domains. Each domain shows some of the speech characteristics in a preferential way. The main domains studied in speech processing are:

- *Time Domain*
- *Spectral Domain*
- *Cepstral Domain*
- *Inverse Model Domain*

Most works in digital speech signal processing are based on these domains. However, other works use new domains derived from the former ones.

In the following section the most important features of each domain are described.

Time Domain

A high quality speech signal possesses a more regular envelope than a low quality speech signal. This fact is more evident in short time intervals. The main phenomena that enable us to distinguish between high quality speech and low quality speech are:

The energy of the speech signal in a short time interval changes considerably between two consecutive intervals in low quality speech whereas in high quality speech there is a less change in energy.

In low quality speech unperiodicity (without periodicity) intervals during voiced sustained speech appear.

Spectral Domain

A low quality speech (a voiced **sustained sound**) has the following characteristics:

- Less regularity of the spectral envelope, mainly in low frequencies.
- More percentage of energy in low frequencies with regard to the total energy.
- Energy blocks in high frequencies. These blocks are caused by glottal noise.
- A great change of the power spectrum from a frame with regard to contiguous frames.

Figure 1. Speech signal in time domain: the five Spanish and sustained vowels are illustrated. The upper figure is a speaker with high quality speech. The lower figure is a speaker with low quality speech.

Figure 2. Sustained voiced sound during a short time interval from a high quality speech (left) and from a low quality speech (right).

Figure 3. Estimated spectrogram from a high quality speech (top) and from a low quality speech (bottom). The five Spanish vowels are pronounced. The sample frequency is 22050 Hz.

High quality speech concentrates its energy around certain formants, mainly the first and the third formants, whereas low quality speech has noise components around the formants.

High quality speech has great spectral wealth. However, low quality speech has a little amount of harmonic component, mainly concentrated in very low frequencies.

The amount of spectral wealth is a characteristic of the voice of a certain speaker. However, the spectral wealth variation in time (during the production of a sustained voiced sound) is indeed an indicator of low quality speech.

Another characteristic in low quality speech (during the production of a sustained voiced sound) is its vari-

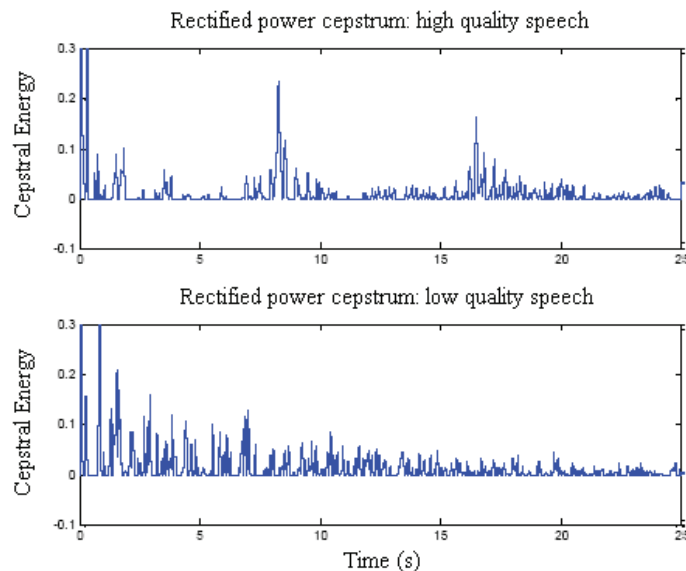

ations in vibration rhythm of vocal folds, i.e. frequency variation in *pitch* frequency.

Cepstral Domain

Characteristics to evaluate the speech quality can be identified in the cepstral domain: envelope of the spectrum, spectral wealth, harmonics and noise components identification, etc. A sustained voiced sound with three times the pitch period in length is used in the cepstral domain.

The spectral wealth of a speech signal can be quantified by the amplitude and width of the cepstral component of the *pitch* frequency. The existence of a peak with great amplitude indicates the presence of notorious energy in that harmonic component. This

Figure 4. A high quality speech (top) and a low quality speech (bottom) in the corrected power cepstrum.

is a characteristic of high quality speech. A reduced width of the cepstral peak corresponding to the pitch indicates the high stability of the *pitch* frequency for three consecutive periods of pitch. This is also a characteristic of high quality speech. Characteristics such as amplitude and width of cepstral peak corresponding to the second harmonic can be also used to distinguish between high and low quality speech. High quality speech possesses a cepstral peak corresponding to the first harmonic narrower than the cepstral peak corresponding to the second harmonic.

Glottal noise in speech signal can be estimated by means of the relationships among different regions in the cepstral domain: the harmonic component (cepstrals components of *pitch* and its harmonics) and noise component (the remaining cepstrals components).

Inverse Model Domain

In this domain, the waveform of air pulse produced by the vocal folds during the production of a sustained voiced sound is estimated. The air pulse is also called residual signal or glottal flux. The estimation is obtained with an inverse filter applied to the speech

signal in order to eliminate the vocal tract effect and lips radiation effect.

The quality of speech can be quantified by some features of the glottal signal such as values of amplitude, time in which vocal folds start to open, time in which vocal folds are completely open, time in which the closing phase of vocal folds starts and different relationships between different times in the glottal cycle: *open quotient*, *speed quotient*, *closing quotient*, etc.

Non Linear Domain

The main commercial systems to evaluate speech quality from a recording objectively (Dr Speech (*Tiger Elemetric*), SSVA (*System for Single Voice Analysis*), MDVP (*Multi-Dimensional Voice Program*), EVA (*Evaluation Vocal Assistee*), CSL (*Computerized Speech Laboratory*) PRAAT, VISHACSRE (*Computerized Speech Research Environment*), MEDIVOZ, etc) do not assess nonlinear characteristics in speech signal.

The most popular model of characterization of the production voice system is a time-variant system, based on linear acoustics theories. It consists of a source/filter model. The existence of variations in spectral amplitude

of speech signal in the fundamental frequency leads us to consider a nonlinear behaviour of speech signal.

A fundamental frequency (f_s) and a subharmonic ($f_s/2$) have been identified in the speech signal (Xue-jing Sun & Yi Xu, 1995). A subharmonic effect is the amplitude modulation or/and the frequency modulation. Other authors indicate that 31% of speakers with pathological speech have **subharmonics** in speech. However, the existence of **subharmonics** has also been identified in high quality speech (Haben, Kost & Papagiannis, 2003). It is estimated that 10.5 % of speakers with healthy speech have **subharmonics**, not being a symptom of an anomalous speech.

There exist two theories to justify the presence of **subharmonics**:

Titze theory (Titze, 1994): **subharmonics** are due to mechanical or geometric asymmetries between vocal folds.

Svec theory (Svec JG, Schutte HK, Miller DG, 1996): subharmonic frequency is due to the combinations of two vibrational modes (biphonation: the presence of two main frequencies) whose frequencies have a 3:2 relation.

Nevertheless, both theories are the same according to (Neubauer J., Eysholdt P., Eysholdt U., Herzel H., 2001), where the authors point out that biphonation is due to asymmetry between the left and right-hand vocal folds or to desynchronization in the back-forth vibration, (Haben C.M., Kost K. & Papagiannis G., 2003). Asymmetry and desynchronization are caused by differences in masses and viscoelastic properties between the vocal folds. This can be modelled by nonlinear phonation. In (Ayache S., Maurice Ouaknine, Dejonckere P., Prindere P. & Giovanni A., 2004) nonlinear models are suggested in order to explain the effect of mucus viscosity of vocal folds (mucus in vocal folds surface generates superficial tension and causes adhesion).

In the traditional model of the vocal tract, sound wave propagation is assumed to be plain wave propagation. However, sound pressure measurements and volume variation measurements are better fitted to a nonlinear model of dynamics fluid. This stems from turbulences (or even periodic turbulences) produced by cavities between the vocal folds and the false vocal folds. This

turbulence excites the vocal tract in the closing phase of vocal folds.

Fractal dimension has been studied by some authors. They conclude that high quality speech signal has a low dimensionality. It is stated (Orlikoff R.F., Baken R. J., 2003), that the amount of aperiodicities in the speech system is an indicator of abnormal phonation and it has been suggested that phase space dimensionality, used for the attractor characterization, could be related to the amount of mass of vocal folds.

QUALITY SPEECH QUANTIFICATION

In the previous section a description of the different features of speech signal in different domains has been given. These features permit us to evaluate the speech quality. Each feature characterizes a physical phenomenon that is involved in voice production. A physical phenomenon can appear in different domains. In this work a set of physical phenomena to make a correct documentation of **voice quality** has been identified. The four physical phenomena identified are:

Voice stability: this is the ability of a speaker to create a constant intensity air flux in order to excite the vocal folds (during a sustained voiced sound). This physical phenomenon is quantified from measurements of speech stability.

Spectral wealth: this is the ability to generate a periodic movement in the vocal folds (during a sustained voiced sound) and produce a voiced excitation of the vocal tract with a great amount of spectral components. This physical phenomenon is quantified computing the pitch frequency stability and by the number of harmonics with high energy in different frequency bands.

Presence of noise: this is related to the presence of glottal noise in speech signal during the phonation of a sustained voiced sound. The presence of glottal noise is due to problems in the closing phase of vocal folds. This physical phenomenon is quantified by measuring the presence of nonstationary noise in speech signal.

Vocal folds irregularities: aperiodicities in speech system are caused by an anomalous working of vocal folds. This is due to irregularities in masses involved in closing phase of vocal folds, asymmetric movement

of vocal folds, and factors related to vocal folds mucus. These phenomena are quantified by means of nonlinear behaviour of speech signal.

An anormal speech shows unless one of the values corresponding to the quantification of the four physical phenomena is out of the normal range. This procedure of quality speech quantification permits us to identify anomalous speech qualities from diverse origins. These four kinds of physical phenomena can be quantified in different domains, existing different objective measurements of speech quality which are capable of quantifying with more or less accuracy a single physical phenomenon.

FUTURE TRENDS

In general, it is impossible to identify pathology in the **fonator system** using only a **speech recording**. This is stated by various authors. This stems from the fact that the acoustic characteristics of two speakers with different pathologies in the **fonator system** can be similar. Even in a visual inspection of the larynx the identity of the pathology cannot be determined. Furthermore, the coexistence of more pathology of the **fonator system** is also frequent.

Nevertheless, several works have focused on identifying the presence of anomalies in the **fonator system**. An automatic detection system of anomalies in speech system has the same diagram as a voice recognition system (see Figure 5).

The “Voice acquisition” block digitalizes speech signal. In this block, a discrimination between speech signal and noise is usually made and the segmentation of speech signal in frames is also carried out.

In the “Parameterization” block the speech quality is quantified using diverse quality measurements for each frame into which the speech signal is divided. The quantification enables us to identify differential characteristics among the different **classification units**.

In our case, the **classification units** are healthy and pathological speech. In this block, each speech frame is turned into a characteristics vector (or measurements vector). Some measurements average certain quantifications of an acoustic characteristic or evaluate its time evolution during the phonation.

An automatic classification of the characteristics vector is made in the “classification” block. The classification systems include Support Vector Machines, Neural Networks, etc.. In our case, the classification for each characteristics vector is between healthy speech and pathological speech.

We propose carrying out clinical studies in order to assess the usefulness of speech quality quantification automatic systems in speech therapy, otolaryngology and phoniatriy. These studies will permit the application of the proposed protocol to measure the speech quality in fields such as the assessment of a surgical operation, documentation of a treatment evolution, medical-legal documentation and telemedicine.

It will be possible to implement automatic classification systems between healthy and pathological speech from databases with different qualities of speech, or even systems capable of automatically giving a measurement of the level of disphonia. These systems can be used in a screening evaluation or in a speech therapist evaluation.

CONCLUSION

In this work, the different physical phenomena which characterize **voice quality** have been identified. These phenomena have been quantified in order to obtain a correct documentation of **voice quality**. The quantification of nonlinear behaviour in signal speech has been introduced to describe in a more realistic way the vocal folds behaviour.

Voice quality quantification allows for the implementation of systems to help in pathologies diagnosis in

Figure 5. Diagram block of the automatic detection system of anomalies in the fonator system

the **fonator system** by means of supervised automatic recognition systems such as Support Vector Machines (SVM) or Neural Networks (NN).

Advances in voice quantification applied to the voice synthesis field will improve naturalness in the production of synthetic voices. The development of automatic mood detection is a possibility (for example, detection of sadness, anger or happiness) with the application of the knowledge acquired in measurements of voice quality. With these systems it will be possible to perceive no verbal language. These systems can be applied to new generations of human-computer interfaces.

KEY TERMS

Characterization or Representation Domains: These are the different spaces into which a signal can be transformed, where certain characteristics of this signal (levels of regularity, levels of noise, similarities, etc) are pronounced of preferential form.

Diagnosis Automatic Intelligent Systems: These are systems which enable the identification of pathological states without the presence of a clinical expert. These systems are oriented to preventive medicine or first screening.

Disphonia: This is the alteration of voice quality. It is mainly caused by laryngeal pathologies. Other different motives to those of a medical nature can produce changes in voice quality, such as, for example, factors related to mood.

GRBAS: Objective measures of speech quality by means of multidimensional clinical measurements based on auditory methods.

Help Systems for Diagnosis: These are systems that help the clinical professionals to identify certain situations that need special attention. They are used generally in tasks of clinical monitorization.

Laryngeal Pathology: Due to different organic injuries (such as malformations, benign injury, inflammations, infections, precancerous and cancerous injuries, traumatisms, or endocrine, neurological and auditive injuries), different functional disphonies (in spoken and sung voice) and of psychiatric origin.

Pitch: Vibration frequency of vocal folds. In fact, there is not complete periodicity in the vibration of vocal folds. That is why it is said that vocal folds have a quasiperiodic movement.

State of the Art in Writer's Off-Line Identification

Carlos M. Travieso González

University of Las Palmas de Gran Canaria, Spain

Carlos F. Romero

University of Las Palmas de Gran Canaria, Spain

INTRODUCTION

Today, advances in Computer Science and the proliferation of computers in modern society are an unquestionable fact. Nevertheless, the continuing importance of orthography and the hand-written document are also beyond doubt.

The new technologies permit us to work with on-line information collecting, but there is still a large quantity of information in our society which requires using algorithms for samples off-line. Security in certain applications requires having biometric systems for their identification; in particular, banking checks, wills, postcards, invoices, medical prescriptions, etc, require the identity of the person who has written them to be verified. The only way to do this is with writer recognition techniques.

Furthermore, many hand-written documents are vulnerable to possible forgeries, deformations or copies, and generally, to illicit misuse. Therefore, a high percentage of routine work is carried out by experts and professionals in this field, whose task is to certify and to judge the authenticity or falsehood of handwritten documents (for example: wills) in a judicial procedure. Therefore nowadays research on writer identification is an active field.

At present, some software tools enable certain characteristics to be displayed and visualised by experts and professionals, but these experts need to devote a great deal of time to such investigations before they are able to draw up conclusions about a given body of writing. Therefore, these tools are not time-saving and nor do they provide a meticulous analysis of the writing. They have to work with graph paper and templates in order to obtain parameters (angles, dimensions of the line, directions, parallelisms, curvatures, alignments, etc.). Moreover, they have to use a magnifying glass

and graph paper in order to measure angles and lines. This research aims to lighten this arduous task.

BACKGROUND

Writer identification is possible because the writing for each person is different, and everyone has intrinsic characteristics. The scientific bases for this idea come from the human brain. If we attempt to write with our less skilful hand, there will be some parts or strokes very similar to the writing which we make using our skilful hand. This is because the brain sends the commands for carrying out the writing and not the hands.

Generally, this effect is projected toward the writing by two types of forces, which are:

- Conscious or known: because it is controlled by the individual's own free will.
- Unconscious: because it escapes the control of the individual's own free will. This is divided into forces of mechanical and emotional means, which behaviour feelings.

Everybody writes using their brain, and simultaneously the handwritten impulse, which is the symbolism of the space in order to obtain the dimensions of the writing, is adapted proportionally, the size of the text being maintained or modified depending on whether the individual is forced to write in a reduced space.

Nowadays, writer identification is a great challenge because such research work has not been as fully developed as that of identification based on fingerprints, hands, face or iris (other biometric techniques), due mainly to the fact that the operation of the brain is very difficult of parameterize. On the other hand, the

above-mentioned techniques use widely researched biometric information.

Most of the characteristics implemented offer information in the vertical and horizontal plane (Zhenyu, Bin, Jianwei, Yuan, & Xinge, 2005) (Zhenyu, Yuan, & Xinge, 2005) (Schlapbach, & Bunke, 2006) (Bulacu, & Schomaker, 2005). We have introduced a new parameter, the proportionality index, which projects in all directions, depending on the selected points.

OFF-LINE WRITER IDENTIFICATION SYSTEM

As with the majority of the works proposed to the present date on biometric recognition, the framework of the system depends on the basic steps showed in figure 1. The images acquisition is a previous step to this system; therefore, this system is an off-line system. The data have to be scanned or photographed in order to build our database.

Data Acquisition

The forensic analysis of hand-written documents requires an extensive database of a known writer's hand-written samples. Therefore samples are gathered of different writers' writing and in turn several samples are taken of each one owing to the temporary invariability.

The creation conditions of a database have to be normalized with different types of paper, pen, and similar place of support (for doing the writing) because our work is centred on the writing and the efficiency of proposed parameters. For these off-line systems, the documents have been generated, and therefore, for the building of the database, the system has to be scanned or a high resolution picture taken. 300dpi on grey scale (8 bits) is a good threshold.

Image Pre-Processing and Segmentation

The first step of the image pre-processing consists of utilizing Otsu's method (or another method), which permits us to determine the necessary grey threshold value to carry out the binarization of the samples (Otsu, 1979).

As result of the binarization, in most cases, the line of writing remains with irregular appearance. For this reason, another pre-processing step is carried out, which enables the line to be smoothed out, thus remaining well defined. This also eliminates the existing noise in the images after the scanning process.

As previous step to the separation of words or connected components, the detection and elimination of the punctuation marks (full stops, accents and commas etc.) is carried out.

Finally, the words which compose the lines of writing are segmented (baselines) and for this, it is necessary to establish limits for each of the words. For this

Figure 1. System of writer identification

estimation, the method of the “Enclosed Boxes” (Ha, Haralick & Phillips, 1995) was used, which provides us the coordinates that will allow us to segment the words. The enclosed boxes are defined as the minimum rectangle that contains the connected component.

Feature Extraction

The calligraphic expert's task is usually to make a statistical list of different quantitative and qualitative measurements carried out on the document in question, and to present this as evidence in a judgment. These include order, legibility, construction of letters, connection, dimension, slant of the letters, space among words and among characters, alignment and skew of the baseline, initial and final stroke, continuity of the stroke, punctuation, control and movement of the ball-point pen.

The developed systems compare the document being tested with the samples of the database, using image digital processing in order to extract the features defined by the system.

We can define three different kinds of features, local, global and texture features (see figure 1).

The local features examine the construction of the individual characters to identify details of certain letters, since it is considered that it is very difficult for a writer to change the way of writing her/his letters. One of the techniques consists of dividing into regions the images of the segmented letters and then for each region to calculate the direction of the gradient; also a geometric description can be obtained by analysing the presence of corners, diagonal, vertical and horizontal lines, direction and angle of the edges and hinges (Zhang, Srihari, & Lee, 2003).

Another way to describe letters is through the pair of coordinated (x,y) of the contour of the connected components and as each writer is considered a generator of a finite number of basic patterns formed by these connected components; it can be characterized by the discrete probability density function of emission of a basic pattern of the strokes (Schomaker, & Bulacu, 2004). Another similar method detects the morphological invariants using an automatic classifier of grapheme; in (Bensefia, Pasquet, & Heutte, 2002), the authors have shown that the variability of the writing can be measured through these invariants because each writer writes the same letters using such patterns or graphemes.

The global features try to describe the properties of the writing and they are statistical measurements extracted from the whole sample of the handwritten document, paragraphs, lines and words to identify (Grening, Sagar, & Leedham, 2005) (Tomai, Zhang, & Srihari, 2004) (Marti, Messerli, & Bunke, 2001). In (Wirotius, Seropia, & Vicent, 2003) a study was carried out on the distribution of gray levels in the pixels of the stroke, calculating the curve of evolution of these levels along sections of the stroke observing that the symmetry with respect to the minimum of the curve presents a great variability according to the writer and the way in which the ball-point pen is located on the paper.

In (Srihari, Cha, Arora, & Lee, 2002) the variation of gray levels is detected by means of its entropy, giving an idea of the pressure applied when writing. Another measurement that provides information of pressure, thickness of the stroke and size of the writing is to count the number of black pixels of the binarized image, which can also allow the movement of the ball-point pen when writing to be estimated indirectly, by means of the quantity average of internal and external contours.

As the contours consist of connected pixel segments, they can be stored as a Chaincode representation where their vertical, horizontal and diagonals components will represent the formation of the stroke.

Other global features are the average slant (Bonzinovic, & Srihari, 1989), localization of the baselines and their skew, height of the ascending, descending and middle body of writing (Marti, Messerli, & Bunke, 2001) (Romero, Travieso, Alonso, & Ferrer, 2007), average width of the characters, behavior of the margins, length of the words and distance between lines and words.

In order to obtain the texture features, the writing sample is viewed as a simple image and not as a manuscript, and therefore each person's writing can be considered as a different texture; applying to it filters of Gabor and co-occurrence Matrixes (Said, Peake, Tan & Baker 1998) for example.

In order for features to represent the writing style, they must fulfill the following requirement: the fluctuations in an individual's writing must be as small as possible, while the fluctuations among different writers must be as great as possible. Each one of these features is evaluated to determine their discrimination index

which allows the utility of each feature to be measured for the identification of writers.

One of the biggest difficulties for automatic identification is the handling of a great variability of writing styles, and there is therefore still some work to be done in the feature extraction stage, since the purpose of this stage is to detect the discriminate features of the writing that characterize the styles of people's writing. Up to now the majority of the characteristics used by the experts are not as yet algorithmically implemented.

In this present work, a list has been created of geometrical parameters of different measurements to analyse documents. In order for the characteristics to represent the style of writing, they should comply with the following requirement: the fluctuations in the writing of a person should be as small as possible, while the fluctuations among different writers should be as large as possible.

This characteristic is included in the list of the following characteristics already developed (Romero, Travieso, Alonso, & Ferrer, 2006) (Hertel, & Bunke, 2003):

- length of the words,
- quantity of pixels in black,
- estimation of the width of the letters,
- height of the medium body of writing,
- heights of the ascending and descending,
- height relation between of the ascending and medium body,
- height relation between descending and medium body,
- height relation between descending and ascending,
- height relation between medium body and the wide of writing.

The quantity of black pixels and the long words will give us an estimation of the dimension and thickness of the line, the width of letters and the height of the medium body. Besides these are the distinctive characteristics of the style of writing.

The estimation of the width of letters is carried out by seeking the row with the greatest quantity of transition of black to white (0 to 1). The number of white pixels between each transition is counted and this result is averaged.

To measure the height of the medium body of the words, the goal is to determine the upper and lower baseline through maximum and minimum values, and to measure the distance between them.

To approach the baselines of each word, it was decided to use the adjustment of minimum mean square error that is based on finding the equation (see expression 1) that is best adjusted to a set of points "n" (Chin, Harvey, & Jennings, 1997). The equation is the following:

$$y = ax + b \quad (1)$$

where the coefficients "a" and "b" determine the lineal polynomial regression by means of the following expressions:

$$a = \frac{n \sum_{i=1}^n x_i y_i - \left(\sum_{i=1}^n x_i \right) \left(\sum_{i=1}^n y_i \right)}{n \sum_{i=1}^n x_i^2 - \left(\sum_{i=1}^n x_i \right)^2} \quad (2)$$

$$b = \frac{\sum_{i=1}^n y_i - a \sum_{i=1}^n x_i}{n} \quad (3)$$

Figure 2. Zones and baselines

Those values of “*a*” and “*b*”, based on the coordinates of minimums or maximums detected in the contour of the word, are different baselines. Minimums are to approach the lower baseline and the maximums for the upper baseline.

The extraction of the proportionality index is a new parameter in our system and in the references. The selection of the points is of random form but with some indications, and therefore we have located the most representative sites as being ascending ones, descendent, terminations, etc. In this paper the most representative points (red points) are displayed in figure 3. For this same word for each writer, we have marked the same red points.

The marked points are united (see Figure 3), and each line between two points is considered as a segment. We have measured the Euclidean length of each segment obtaining a mean and a standard deviation. These are new and novel parameters, which provide information from every direction of a word.

Classification System

The problem of the identification of writers can be seen according to two different approaches (see Figure 4); the first approach is the verification that allows us to determine whether two documents were written by the same person or by two different people.

The second approach is the identification that consists of recognising a writer among a set of *N* candidates. This case can be seen as a problem of classification of *N* classes. Due to the potentially great number of candidates, the decision is based on the measurement of the nearest neighbour; its advantage is that it identifies the writer directly.

Both approaches resort to some method of similarity measurement or distances between the samples; and the system must be trained with a set of handwritten samples belonging to each candidate (supervised classification). The most commonly used classification methods are nearest *k*-neighbours (Hertel, & Bunke, 2003), Neuro-

Figure 3. Segments obtained when points are united (proportionality index)

Figure 4. Difference between identification and verification

nal Network (Bishop, 1995), Hidden Models Markov (Juang, & Rabiner, 1992), Gaussian Mixture Models (Schlapbach, & Bunke, 2006), etc.

In the following table, we can see a comparison of different methods, showing the type of samples, number of writers and its success rates.

FUTURE TRENDS

The future tendency is the use of the Graphology, as fundamental element to establish new features, because experts or professionals have more years of experience and credibility in this field. The quantitative implementation of these features will result in positive growth in terms of success rates.

CONCLUSION

Writer identification systems could end up as a powerful tool to help Calligraphic Experts, since it will allow them to reduce the time invested in the analysis of certain features of the writing, since the system will develop the detection, extraction, comparison, classification and recognition tasks. Logically, it will not replace them because it is impossible to equal the observation power of the human in this complex application; therefore there will always be features that will have to be analyzed by the experts because they are very difficult to implement algorithmically.

Finally, off-line writer identification is an open research field, where the operation of different and new methods is both improving and spreading in terms of usage.

KEY TERMS

Biometric System: This is a system which identifies individuals using behaviour or physical characteristics.

Classification System: Learning algorithm which generates automatic results from a features input. This system generally has as many outputs as classes for classifying.

Feature Extraction: This is a process which is used to obtain certain characteristics which are intrinsic and discriminate of a thing.

Image Pre-Processing: Set of tools applied to the images in order to provide other improved images for other tasks.

Off-Line System: A system whose operation is based on data that have been acquired before of its operation.

On-Line System: A system whose operation is based on data which are acquired during its operation.

Supervised Classification: This is a system that generates a model using training samples with labels, and it uses that model in order to establish an evaluation or test with other samples without labels.

Writer Identification: The application of biometric identification by handwriting. Full texts or just several words can be used.

State-of-the-Art on Video-Based Face Recognition

INTRODUCTION

Over the past few years, face recognition has gained many interests. Face recognition has become a popular area of research in computer vision and pattern recognition. The problem attracts researchers from different disciplines such as image processing, pattern recognition, neural networks, computer vision, and computer graphics (Zhao, Chellappa, Rosenfeld & Phillips, 2003).

Face recognition is a typical computer vision problem. The goal of computer vision is to understand the images of scenes, locate and identify objects, determine their structures, spatial arrangements and relationship with other objects (Shah, 2002). The main task of face recognition is to locate and identify the identity of people in the scene. Face recognition is also a challenging **pattern recognition** problem. The number of training samples of each face class is usually so small that it is hard to learn the distribution of each class. In addition, the within-class difference may be sometimes larger than the between-class difference due to variations in illumination, pose, expression, age, etc.

The availability of the feasible technologies brings face recognition many potential applications, such as in face ID, access control, security, surveillance, smart cards, law enforcement, face databases, multimedia management, human computer interaction, etc (Li & Jain, 2005).

Traditional still image-based face recognition has achieved great success in constrained environments. However, once the conditions (including illumination, pose, expression, age) change too much, the performance declines dramatically. The recent FRVT2002 (Face Recognition Vendor Test 2002) (Phillips, Grother, Micheals, Blackburn, Tabassi & Bone 2003) shows that the recognition performance of face images captured in

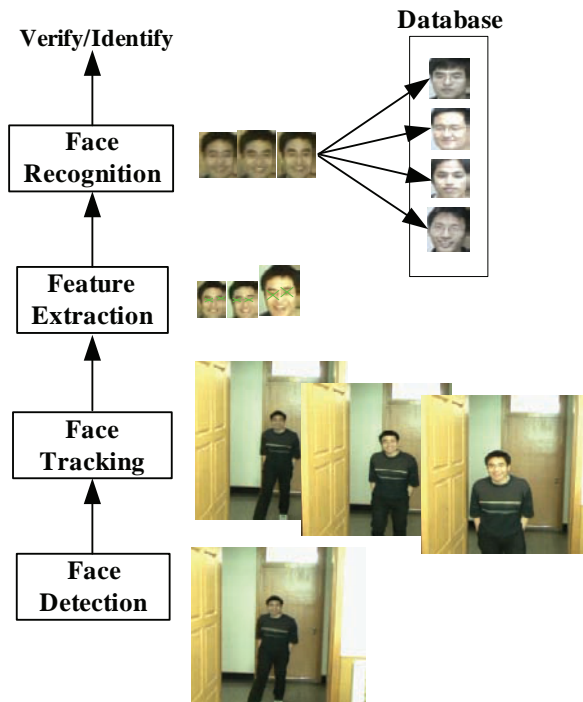

an outdoor environment and different days is still not satisfying. Current still image-based face recognition algorithms are even far away from the capability of human perception system (Zhao, Chellappa, Rosenfeld & Phillips, 2003). On the other hand, psychology and physiology studies have shown that motion can help people for better face recognition (Knight & Johnston, 1997; O'Toole, Roark & Abdi, 2002). Torres (2004) pointed out that traditional still image-based face recognition confronts great challenges and difficulties. There are two potential ways to solve it: video-based face recognition technology and multi-modal identification technology. During the past several years, many research efforts have been concentrated on video-based face recognition. Compared with still image-based face recognition, true **video-based face recognition** algorithms that use both spatial and temporal information started only a few years ago (Zhao, Chellappa, Rosenfeld & Phillips, 2003).

This article gives an overview of most existing methods in the field of video-based face recognition and analyses their respective pros and cons. First, a general statement of face recognition is given. Then, most existing methods for video-based face recognition are briefly reviewed. Some future trends and conclusions are given in the end.

BACKGROUND

From a general point of view, a complete video-based face recognition system includes face detection module, face tracking module, feature extraction module and face recognition module. Face detection is at the bottom layer. The task of face detection is to determine the spatial position and pose of the face(s). Face tracking is at the middle layer. It follows the continuous change

Figure 1. A general framework of video-based face recognition system

of face position over time. Feature extraction is at a higher layer. Its task is to locate the position of facial features such as eye, nose, etc, and pull out related information. Face recognition module is at the top layer. The face recognition module identifies or verifies the input face(s), with the help of databases. Figure 1 gives the general framework of video-based face recognition system, with a flowchart and some examples.

In this article, the focus will be on the top layer of face recognition systems—face recognition module. The general statement of **face recognition** can be defined as: given still or video images of a scene, identify or verify one or more persons in the scene using a stored database of faces (Zhao, Chellappa, Rosenfeld & Phillips, 2003). The still image-based face recognition usually refers to the process in which the input is a still image. On the other side, the video-based face recognition often refers to the process in which the input is a shot of video. The database can be also still image(s) or video. Therefore, according to different modalities of the input and database, four different scenarios of face recognition can be distinguished. Table 1 shows these four different scenarios of face recognition. **Video-**

based face recognition usually refers to both “Video - Image(s)” face recognition and “Video - Video” face recognition, that is, with video input.

Compared with still image-based face recognition, video-based face recognition can utilize the temporal and spatial information available in the video. It’s widely believed that video-based face recognition is more promising than still image-based face recognition. However, there also exist some difficulties in video-based face recognition, such as low-resolution face images, large variations of scale, illumination change, pose change, and occasionally occlusion in video. It is worth noting that if the time information of video is not considered, the video-based face recognition becomes the multiple-still-images input face recognition.

VIDEO-BASED FACE RECOGNITION

According to the classification shown in Table 1, four scenarios of face recognition will be reviewed separately. The emphases will be put on “Video - Image(s)” face recognition and “Video - Video” face recognition. For simplicity, the position of the face in the video is assumed to be known in advance.

“Image - Image(s)” Face Recognition

“**Image - Image(s)**” face recognition is the traditional still image-based face recognition. Numerous still image-based face recognition methods have been developed during the past few decades (Zhao, Chellappa, Rosenfeld & Phillips, 2003). Among them, global feature matching methods, such as Eigenface (Turk & Pentland, 1991), Fisherface (Belhumeur, Hespanha & Kriegman, 1997) and Bayesian (Moghaddam, Jebara & Pentland, 2000); and local feature matching methods, such as Elastic Bunch Graph Matching (EBGM) (Wiskott, Fellous, Krueger & Malsburg, 1997), are the widely used face recognition approaches. Recently, 3D deformable models (Banz & Vetter, 2003) and Local Binary Pattern (LBP) (Ahonen, Hadid & Pietikäinen, 2006) are the newly-emerging methods. Traditional still image-based face recognition has been widely used in biometric authentication, information security, etc.

Table 1. Four different scenarios of face recognition

| Input \ Database | Still-Image(s) | Video |
|------------------|------------------|---------------|
| Still-Image | Image - Image(s) | Image - Video |
| Video | Video - Image(s) | Video - Video |

“Image - Video” Face Recognition

“Image - Video” face recognition is to identify or verify a given face in the stored video sequences. “Image - Video” face recognition is also called human face-based video retrieval. Typical scenes includes finding suspects in the recorded surveillance video or finding a person in the film or news video from a given face image. Theoretically, it should do video preprocessing first, such as shot extraction. Then, face detection and tracking are performed to obtain the video shot of every face. Face recognition is conducted in the last step. Due to the complex scenes in such videos (film, news, surveillance video), most literature focuses on video preprocessing phase (Arandjelović & Zisserman, 2005b). In recent years, some scholars applied 3D model for television people retrieval (Everingham & Zisserman, 2004).

“Video - Image(s)” Face Recognition

“Video - Image(s)” face recognition can be formulated as follows: given a shot of video, identify or verify the face inside by using a still-image(s) database. With the wide-spread usage of video acquisition hardware, there exist many video sequences in the application of security authentication, video surveillance, etc. At the same time, most existing databases are still-image(s) database. Therefore, how to make better use of the input video is of important value in real applications.

Traditional approaches can be roughly divided into two categories: one is to perform face tracking until a facial image satisfies certain rules (such as size, pose). Then traditional still image-based face recognition methods are applied. The disadvantages of such approaches are the difficulty of defining the rules and not making full use of all information in the video. Another is to perform still image-based face recogni-

tion for each tracked face and combine the recognition results (using combining rules, for example, maximum cumulative probability or a majority vote). The disadvantages of such approaches are the randomness of the combining rules.

In recent years, some researchers try to make use of temporal and spatial information in the video. Zhou et al. (2003) proposed a Bayesian framework based face recognition and tracking which attempts to resolve uncertainties in tracking and recognition simultaneously. A time series state space model, which characterizes the kinematics using a motion vector and the identity using an identity variable, is employed to fuse temporal information. The joint posterior distribution of the motion vector and the identity variable is estimated at each time instant and then propagates to the next time instant. Marginalization over the state vector yields a robust estimate of the posterior distribution of the identity variable. The **sequential importance sampling (SIS)** algorithm was used to estimate the posterior distribution. SIS approximates the posterior density function by a set of random particles with associated weights. Experimental results show the effectiveness of the algorithm.

Li et al. (2001, 2002) applied facial features tracking and face tracking for verification. The basic idea is that if the input is a true face (corresponding to the identity in the database), the tracking trajectories of the facial features or face appearance are basically the same. The corresponding mathematical model is that the distribution of motion vector will have a peak when the face is a true input. Otherwise, the input is an imposter. SIS is also applied to the posterior probability distribution of state variables. However, the estimated probability density needs a large number of particles to characterize the distribution. As a result, the complexity of the algorithm is increased.

“Video - Video” Face Recognition

“**Video - Video**” face recognition refers to the cases in which both the input and database are shots of video. Based on the use of the information in the video, the existing literatures have the following description methods to represent a shot of video:

1. A vector (corresponding to one frame of the video).
2. A matrix (corresponding to all frames of the video).
3. Probability Density Function (PDF).
4. Dynamic model.
5. Manifold.

Based on the above description methods, “Video – Video” face recognition becomes matching of different description methods. Table 2 shows all possible similarity measures (distances) between two description methods. In Table 2, d stands for the distance or similarity of two models. $f(X)$ stands for probability addition, $M(X)$ stands for majority voting, $D(X)$ stands for the posterior probability.

Some representative methods of “Video - Video” face recognition are briefly introduced below. Torres et al (2002) created a person specific **Principal Component Analysis (PCA)** subspace for each face in the database. The residual distance between the face in one frame and the PCA subspace is used as similarity measure for video indexing. McKenna et al (1997) employed **Gaussian Mixture Model (GMM)** in the reduced PCA subspace to describe each face class. The posterior probability of each face in each frame is computed and the cumulative probability is used as similarity measure. Yamaguchi et al (1998) established PCA subspace for both the input and database video. The distance between the two subspaces is determined

by the angle between two subspaces. To further handle the change of illumination, gestures, facial expressions, etc., Fukui & Yamaguchi (2003) further proposed the constraint subspace that includes only the effective component for recognition.

Arandjelovi et al (2005a) used GMM to learn the face distribution. The basis of the approach is the semi-parametric estimation of probability densities confined to intrinsically low-dimensional, but highly nonlinear face manifolds embedded in the high dimensional image space (Arandjelović, Shakhnarovich, Fisher, Cipolla & Darrell, 2004). The **Kullback-Leibler divergence** is adopted as the similarity measure.

Zhou et al. (2003) used the probabilistic model described in previous section. An exemplar-based learning is adopted to automatically select video representatives. The exemplar index is also employed as the state vector. The joint probability density distribution is estimated by sequential importance sampling. Finally, the identity variable is calculated by marginalization. Liu and Chen (2003) proposed a video-based face recognition algorithm based on **Hidden Markov Model (HMM)** which incorporates both the temporal and spatial information. Lee et al. (2003, 2005) approximated face manifolds by a finite number of linear subspaces and used temporal information to robustly estimate the dynamics of the linear subspaces.

Li et al (2001a, 2001b) employed the manifold to represent a shot of video. A 3D shape model is built from 2D images, a shape-and-pose-free textures model and an affine geometrical model. Then, **Kernel Discriminant Analysis (KDA)** is performed to extract the non-linear discriminating features. The identify surfaces are then constructed from these discriminating features. Face recognition is performed by computing **trajectory distance** between the input and database video trajectories.

Table 2. Similarity measures (distance) between two description methods

| Database Input | Vector(x) | Matrix(X) | Probability(f) | Dynamic Model(D) | Manifold(M) |
|----------------------|---------------|---------------|--------------------|----------------------|-----------------|
| Vector(x) | $d(x, x)$ | $d(x, X)$ | $f(x)$ | $D(x)$ | $M(x)$ |
| Matrix(X) | $d(X, x)$ | $d(X, X)$ | $f(X)$ | $D(X)$ | $M(X)$ |
| Probability(f) | $f(x)$ | $f(X)$ | $d(f, f)$ | \ | \ |
| Dynamic Model(D) | $D(x)$ | $D(X)$ | \ | $d(D, D)$ | $d(D, M)$ |
| Manifold(M) | $M(x)$ | $M(X)$ | \ | $d(M, D)$ | $d(M, M)$ |

Table 3. Typical algorithms for “Video - Video” face recognition

| Authors | Input Description | Database Description | Measure |
|-------------------|----------------------|--|----------------------------------|
| Torres et al | Vector(x) | PCA subspace(X) | residual error, $d(x, X)$ |
| McKenna et al | Matrix(X) | GMM(f) | cumulative probability, $f(X)$ |
| Yamaguchi et al | Matrix(X) | PCA subspace(X) | angle distance, $d(X, X)$ |
| Arandjelovi et al | PDF(f) | GMM(f) | K-L divergence, $d(f, f)$ |
| Zhou et al | Dynamic Model(D) | Exemplars(X) | posterior probability, $D(X)$ |
| Liu et al | Dynamic Model(D) | HMM(D) | posterior probability, $d(D, D)$ |
| Lee et al. | Dynamic Model(D) | Finite number of linear subspaces(M) | posterior probability, $d(D, M)$ |
| Li et al | Manifold(M) | Manifold(M) | trajectory distance, $d(M, M)$ |

Some characteristics of the above reviewed algorithms are listed in Table 3.

FUTURE TRENDS

Video-based face recognition has been actively studied in recent years. How to better exploit both spatial and temporal information in the video sequence is the focus point.

An individual face manifold under various changes (such as expression, pose, illumination, etc) is non-convex and nonlinear. Effective features which can discriminative different classes and tolerate within-class variations are the key for both still image-based and video-based face recognition.

Another trend is to generate a 3D face model from video. See (Zhang, Liu, Dennis, Cohen, Hanson, & Shan, 2004) for an example. The 3D face model can overcome the problem caused by large change of pose and illumination. However, the complexity of 3D model is high.

CONCLUSION

In this article, based on the classification of different scenarios of face recognition methods, Four groups of techniques—the “Image - Image(s)” face recognition, “Image - Video” face recognition, “Video - Image(s)” face recognition, “Video - Video” face recognition are

reviewed. Most existing methods of video-based face recognition are surveyed. Their respective advantages and disadvantages are also provided. Some trends of video-based face recognition are summarized. In the future, the approaches will be further investigated to drive more applications.

KEY TERMS

Biometric Authentication: Technologies rely on physical characteristics that are unique for each person to ascertain the identity of an individual.

Face Detection: A computer technology that determines the locations and sizes of human faces in digital images.

Face Recognition: Given still or video images of a scene, identify or verify one or more persons in the scene using a stored database of faces.

Face Tracking: A computer technology that determines the continuous location of the face(s) on each frame of the image sequence.

Human Face Based Video Retrieval: A process that one searches the video sequences to find the face shot according to the query face image.

Particle Filters: Techniques which also known as Sequential Monte Carlo methods (SMC), are sophisticated model estimation techniques based on simulation.

Sequential Importance Sampling: A very common particle filter algorithm that approximates the probability density functions by a set of random samples with associated weights.

Video-Based Face Recognition: Given a video containing face(s), identify or verify one or more persons using a stored database.

Stationary Density of Stochastic Search Processes

INTRODUCTION

The optimization of a cost function which has a number of local minima is a relevant subject in many important fields. For instance, the determination of the weights of learning machines depends in general on the solution of global optimization tasks (Haykin, 1999). A feature shared by almost all of the most common deterministic and stochastic algorithms for continuous non – linear optimization is that their performance is strongly affected by their starting conditions. Depending on the algorithm, the correct selection of an initial point or set of points have direct consequences on the efficiency, or even on the possibility to find the global minima. Of course, adequate selection of seeds implies prior knowledge on the structure of the optimization task. In the absence of prior information, a natural choice is to draw seeds from a uniform density defined over the search space. Knowledge on the problem can be gained through the exploration of this space.

In this contribution is presented a method to estimate probability densities that describe the asymptotic behavior of general stochastic search processes over continuously differentiable cost functions. The relevance of such densities is that they give a description of the residence times over the different regions of the search space, after an infinitely long exploration. The preferred regions are those which minimize the cost globally, which is reflected in the asymptotic densities. In first instance, the resulting densities can be used to draw populations of points that are consistent with the global properties of the associated optimization tasks.

BACKGROUND

Stochastic strategies for optimization are essential to most of the heuristic techniques used to deal with complex, unstructured global optimization problems (Pardalos, 2004). The roots of such methods can be traced back to the Metropolis algorithm (Metropolis, Rosenbluth, Rosenbluth, Teller & Teller, 1953), introduced in the early days of scientific computing to simulate the evolution of a physical system to thermal equilibrium. This process is the base of the simulated annealing technique (Kirkpatrick, Gellat & Vecchi, 1983), which makes use of the convergence to a global minimum in configurational energy observed in physical systems at thermal equilibrium as the temperature goes to zero.

The method presented in this contribution is rooted in similar physical principles as those on which simulated annealing type algorithms are based. However, in contrast with other approaches (Suykens, Verrelst & Vandewalle, 1998) (Gidas, 1995) (Parpas, Rustem & Pistikopoulos, 2006), the proposed method considers a density of points instead of Markov transitions of individual points. The technique is based in the interplay between Langevin and Fokker – Planck frameworks for stochastic processes, which is well known in the study of out of equilibrium physical systems (Risken, 1984) (Van Kampen, 1992). Fokker - Planck equation has been already proposed for its application in search algorithms, in several contexts. For instance, it has been used to directly study the convergence of populations of points to global minima (Suykens, Verrelst & Vandewalle, 1998), as a tool to demonstrate the convergence of simulated annealing type algorithms (Parpas, Rustem & Pistikopoulos, 2006) (Geman & Hwang, 1986), or

as a theoretical framework for Boltzmann type learning machines (Movellan & McClelland, 1993) (Kosmatopoulos & Christodoulou, 1994). In the context of global optimization by populations of points, it has been proposed that the populations evolve under the time – dependent version of the Fokker – Planck equation, following a schedule for the reduction of the diffusion constant D (Suykens, Verrelst & Vandewalle, 1998).

In our approach, the stationary version of the Fokker – Planck equation is used to learn the long – term probability density of a general stochastic search process. This is achieved using linear operations and a relatively small number of evaluations of the given cost function.

STATIONARY DENSITY ESTIMATION ALGORITHM

Consider the minimization of a cost function of the form $V(x_1, x_2, \dots, x_n, \dots, x_N)$ with a search space defined over $L_{1,n} \leq x_n \leq L_{2,n}$. A stochastic search process for this problem is modeled by

$$\frac{dx_n}{dt} = -\frac{\partial V}{\partial x_n} + e(t) \quad (1)$$

where $e(t)$ is an additive noise with zero mean. Equation (1), known as Langevin equation in the Statistical Physics literature (Risken, 1984) (Van Kampen, 1992), captures the basic properties of a general stochastic search strategy. Under an uncorrelated Gaussian noise with constant strength, Eq. (1) represents a search by diffusion, while a noise strength that is slowly varying in time gives a simulated annealing process. Notice that choosing an external noise of infinite amplitude, the dynamical influence of the cost function over the exploration process is lost, leading to a blind search. The model given by Eq. (1) can be interpreted as a nonlinear dynamical system composed by N interacting particles. The temporal evolution of the probability density of such a system is described by a linear differential equation, the Fokker – Planck equation (Risken, 1984) (Van Kampen, 1992),

$$\frac{dp}{dt} = \frac{\partial}{\partial x} \left[\frac{\partial V}{\partial x} p \right] + D \frac{\partial^2 p}{\partial x^2} \quad (2)$$

The approach proposed in this article is based on the notion of an infinitely long exploration of the search space. In the present model setup for the search, the process converges to a state described by the stationary solution of Eq. (2) (Berrones, 2007). The form of this solution is of the well known Boltzmann type (Risken, 1984) (Van Kampen, 1992). For optimization or deviate generation purposes, its direct use would imply a high computational cost. Instead, a form of Gibbs sampling is proposed in order to estimate the marginal probability density $p(x_n)$ (the details of the following discussion can be consulted in (Berrones, 2007)). The one dimensional projection of Eq. (2) at $t \rightarrow \infty$ leads to the following equation for the conditional cumulative distribution, $y(x_n | \{x_j \neq x_n\})$

$$\frac{d^2 y}{dx_n^2} + \frac{1}{D} \frac{\partial V}{\partial x_n} \frac{dy}{dx_n} = 0$$

$$y(L_{1,n}) = 0, \quad y(L_{2,n}) = 1 \quad (3)$$

Therefore, the estimation of the analytical form of $y(x_n | \{x_j \neq x_n\})$ can be achieved by the substitution of the expansion

$$y = \sum_{l=1}^L a \phi_l(x_n) \quad (4)$$

into Eq. (3). The distribution obtained in this way can be used to draw points from the conditional density $p(x_n | \{x_j \neq x_n\})$. According to the principles of Gibbs sampling (Geman & Geman, 1984), the iteration of the previous steps over the N variables will produce a population sampled from the corresponding marginal densities $p(x_n)$. However, in our setup all the information needed to characterize the densities is contained in the coefficients of the expansion (4). In this way, the stationary marginal densities associated to the N variables of the optimization problem, are learned through the averages of the coefficients over the iteration of the random deviate generation process. We call this basic procedure a Stationary Density Estimation Algorithm (SDEA). We have also named the method Stationary Fokker – Planck Machine (SFPM) in (Berrones, 2007), in order to indicate its relation with other methods (Suykens, Verrelst & Vandewalle, 1998) that make use of the Fokker – Planck equation to learn statistical features of stochastic search processes. However, in

(Suykens, Verrelst & Vandewalle, 1998) the Fokker–Planck equation is used to study the evolution of finite populations of points from out of equilibrium states. This contrast with our approach, which estimate the equilibrium densities on the entire search space.

As an example, the SFPM algorithm is tested on the Levy No. 5 function, an important benchmark problem with about 760 local minima and one global optimum (Parsopoulos & Vrahatis, 2002),

$$f(x) = \sum_{i=1}^5 i \cos((i-1)x_1 + i) \sum_{j=1}^5 j \cos((j+1)x_2 + j) + (x_1 + 1.42513)^2 + (x_2 + 0.80032)^2 \quad (5)$$

with a search space given by the hypercube $[-10, 10]$. The direct implementation of a stochastic search through Eq. (1) would imply the simulation of a stochastic dynamical system composed by two particles with highly nonlinear interactions. By our methodology, in contrast, we are able to obtain adequate densities by linear operations and performing a moderate number of evaluations of the cost function. In Fig.1 the densities generated by 10 iterations of the estimation algorithm with parameters $L=50$ and $D=200$ are shown. The obtained densities are perfectly consistent with the global properties of the problem, since the known global optimum at the point $(-1.3068, -1.4248)$ is contained in the regions with highest probability. The computational

effort is low in the sense of the required number of cost function evaluations, given by $2(L-1)MN=1960$. This is comparable to the effort needed by advanced techniques based on populations in order to obtain good quality solutions for the same problem (Parsopoulos & Vrahatis, 2002). Our approach, however, is not limited to the convergence to good solutions, but it estimates entire densities. The implications of this in, for instance, the definition of probabilistic optimality criteria, are currently under research by us.

FUTURE TRENDS

In our opinion the theory and results presented so far have the potential of considerably enrich the tools for global optimization. The characterization of optimization problems in terms of reliable probability densities may open the door to new insights into global optimization by the use of probabilistic and information–theoretic concepts. From a more practical standpoint, the proposed methodology may be implemented in a variety of ways in order to improve existing or construct new optimization algorithms.

CONCLUSION

This work presents a methodology to estimate the probability density function of optimization problems with

Figure 1. Probability densities, $p(x_1)$ and $p(x_2)$ respectively, generated by 10 iterations of the stationary density estimation algorithm for the Levy No. 5 function. The parameters of the algorithm are $L = 50$ and $D = 200$. The global optimum is in the region of maximum probability.

a continuous differentiable cost function, using linear operations and a moderate number of evaluations of the cost function. The generalization to constrained problems appears to be straightforward. This is expected taking into account that the proposed method makes use of linear operations only. In this way, constraints may enter into Eq. (1) as additional nonlinear terms, with no essential increment in computational cost. For instance, combinations of sigmoidal functions can be used for the representation of the constraints as forces produced by energy barriers.

KEY TERMS

Configurational Energy: Refers to the potential energy associated with the various forces within the elements of a physical system.

Diffusion Constant: Measures the degree of randomness in a diffusion process. The diffusion constant is proportional to the mean square distance moved by particles under diffusion in a given time interval.

Diffusion Process: Random displacement of particles in a physical system due to the action of a temperature.

Gibbs Sampler: A procedure to sample the marginal densities from a high dimensional distribution using one dimensional conditional probabilities.

Heuristic: Is any algorithm that finds a good quality solution to a problem in a reasonable run time.

Learning Machine: This term refers to the development of techniques for automatic extraction of patterns from massive data sets and to the construction of deductive rules. In the context of this article, this concept deals with the automatic learning of densities in global optimization problems.

Random Deviate Generation Process: A process which generates random numbers according to a specific probability distribution.

Search Space: This is the set of all the feasible solutions for an optimization problem.

Stochastic Search: Is an optimization algorithm which incorporate randomness in its exploration of the search space.

Thermal Equilibrium: State in which a physical system is described by probability measures that are time independent.

Statistical Modelling of Highly Inflective Languages

Mirjam Sepesy Maučec

University of Maribor, Slovenia

Zdravko Kačič

University of Maribor, Slovenia

INTRODUCTION

A language model is a description of language. Although grammar has been the prevalent tool in modelling language for a long time, interest has recently shifted towards statistical modelling. This chapter refers to speech recognition experiments, although statistical language models are applicable over a wide-range of applications: machine translation, information retrieval, etc.

Statistical modelling attempts to estimate the frequency of word sequences. If a sequence of words is $s = w_1 w_2 \dots w_k$, the probability can be expressed as:

$$P(s) = P(w_1 w_2 \dots w_k) =$$

$$\prod_{i=1}^k P(w_i | w_1 \dots w_{i-1}) \approx \prod_{i=1}^k P(w_i | w_{i-n+1} \dots w_{i-1}).$$

It is reasonable to simplify this computation by approximating the word sequence generation as a $(n-1)$ -order Markov process (Jelinek, 1998). Bigram ($n=2$) and trigram ($n=3$) models are common choices. Although we have limited the context, such models have a vast number of probabilities that need to be estimated. The text available for building the model is called the ‘training corpus’ and, typically contains many millions of words. Unfortunately, even in a very large training corpus, many of the possible n -grams are never encountered. This problem is addressed by smoothing techniques (Chen & Goodman, 1996).

Which is the best modelling unit? Words are a common choice, but units smaller (or larger) than words can also be used. Word-based n -gram is best suited to modelling the English language (Jelinek, 1998). Inflective languages have several characteristics, which harm the prediction powers of standard models.

In general, all Indo-European languages are inflective but a serious problem arises regarding languages which are inflected to a greater extent (e.g. Russian, Czech, Slovenian). Agglutinative languages (e.g. Hungarian, Finnish, Estonian) have even more complex inflectional grammar where, besides inflections, compound words are a big problem. Inflective languages add inflectional morphemes to words. Inflectional morphemes indicate the grammatical information of a word (for example case, number, person, etc.). Inflectional morphemes are commonly added by affixing, which includes prefixing (adding a morpheme before the base), suffixing (adding it after the base), and much less common, infixing (adding it inside the base). A high degree of affixation contributes to the explosion of different word forms, making it difficult, even impossible, to robustly estimate language model probabilities. Rich morphology leads to high OOV (Out-Of-Vocabulary) rates and, therefore, data sparsity is the main problem.

This chapter focuses on modelling unit choice for inflective languages with the aim of reducing data sparsity. Linguistic and data-driven approaches were analyzed for this purpose.

BACKGROUND

Class-Based Language Models

Some words are similar in their morphological, syntactic or semantic functions. In class-based language models, similar words are grouped into classes in order to improve the robustness of parameter estimation:

$$P(w_i | w_{i-1}) = P(w_i | C(w_i)) \cdot P(C(w_i) | C(w_{i-1})).$$

C denotes the deterministic mapping of words into classes. Non-deterministic mapping can also be derived at, where one word can belong to many classes. A model is also applicable, where the word is directly conditioned by the classes of previous words. The idea behind class-based models is parameter-set reduction. There are far fewer free parameters to estimate in a class-based model than in a word-based model.

Words in the same class are similar in a certain way. This similarity can be defined, based on certain external knowledge or statistical criterion. The best known example of clustering using linguistic knowledge is clustering by POS (Part Of Speech). Eight POSs are defined in traditional English grammar: noun, verb, adjective, adverb, pronoun, preposition, conjunction, and interjection. This set of classes is, however, too small for modelling inflective languages. Those classes that reflect additional grammatical features (gender, case, number, tense, etc.) are more suitable.

Linguistic classes were examined for several languages, which are more or less inflective. A language model for French combined POS classes with a component based on lemmas (El-Beze & Derouault, 1990). In the language model for Czech, words were clustered into 410 morpho-syntactic classes (Nouza & Nouza, 2004). 1300 classes were used in another experiment for Czech (Kolar, Svec & Psutka, 2004). Class-based models with linguistic classes also proved to be successful for Spanish (Casillas, Varona & Torres, 2004).

Data driven classes are automatically derived at by statistical means. IBM pioneered this approach (Brown, de Souza, Mercer, Della Pietra & Lai, 1992). In their approach, words are clustered using a greedy algorithm that tries to minimize the loss of mutual information between classes incurred during the merge. The number of classes must be defined in advance. The algorithm continues to merge pairs of classes until the desired number of classes has been obtained. Another greedy approach uses the exchange algorithm (Martin, Liermann & Ney, 1995). Each word is moved from its class to another one if it maximizes mutual information between classes.

Data-driven class-based language models have been built for many inflective languages. For French they show improved performance on small and large corpora (Zitouni, 2002). The results have been improved by using a hierarchical language model with variable-length class sequences, based on 233 grammatical classes. In experiments on the Russian language, the best results

were obtained by using 500 classes (Whittaker & Woodland, 2003). The results were further improved when a class-based model was combined with a word-based model.

Lots of data must be available to derive at classes automatically from the data instead of using external knowledge sources.

Language Models Based on Sub-Word Units

Given the difficulties in language modelling based on full word forms it would be desirable to find a method of decomposing word forms into their morphological components and to build a more robust language model based on probabilities involving individual morphological components.

Lexicons exist for some languages which contain information about the morphological components of words. In experiments on Czech, words were decomposed into stems and endings using a Czech Morphological Analyzer, and were then used as modelling units (Byrne, Hajič, Ircing, Krbeč & Psutka, 2000). Morpheme-based language models were also studied for the Korean language, where a word-phrase is an agglomerate of morphemes (Kwon & Park, 2003). Sub-word units are also used when modelling agglutinative languages where, besides inflections, compound words are very common (Szarvas & Furui, 2003). Morphological sub-word units have also been proved for Turkish (Erdoğan, Büyük & Oflazer, 2005). The language model's constraints were represented by a weighted finite state machine.

Many languages do not have developed morphological analysers. Data-driven discovery of a language's morphology is used in such cases. It is common for data-driven approaches to outperform linguistic ones. Morphemic suffixes were discovered by Minimum Description Length (MDL) analysis (Brent, Murthy & Lundberg, 1995). MDL analysis has been used for morphological segmentation for various European languages (Goldsmith, 2001). An algorithm for learning morphology using latent semantic analysis was also discovered (Schone & Jurafski, 2000). This algorithm only extracts affixes when the stem and stem-affix are sufficiently similar semantically. The language model for Russian also improves when using data-driven sub-word units (Whittaker & Woodland, 2000). Language-independent algorithms for discovering word

fragments based on MDL have been presented for Finnish language (Hirsimäki, Creutz, Siivola, Kurimo, Virpioja, & Pylkkönen, 2005). The authors report that word fragments obtained using grammatical rules gave worse results than fragments obtained by data-driven algorithms. They improved speech recognition results furthermore by clustering morph n -gram histories (Virpioja & Kurimo, 2006). The same kinds of comparisons with similar conclusions have also been done for the Turkish and Estonian languages.

LANGUAGE MODEL OF INFLECTIVE LANGUAGE

Our work is mainly devoted to the highly inflective Slovenian language. It is a South Slavic language. It shares its characteristics, in varying degrees, with many other inflective languages, especially Slavic.

As in the case of other inflective languages, we concentrate on reducing the perceived data sparsity. The techniques we investigate are language-independent and, as such, also applicable to other highly inflective languages.

Class-Based Language Models of the Slovenian Language

In our first study, the use of data-driven classes was examined. In (Sepesy Maučec, Brest, Kačič & Žumer, 2000) we described an improved algorithm for word clustering. The main idea was to replace the systematic replacement of words between classes with a randomized one. Secondly, instead of replacing one word after another, a randomly selected group of words was replaced at once. The pseudocode of the algorithm is:

1. Set up initial mapping
2. Compute initial train set perplexity PP
3. while (not stopping criterion is met) do begin
4. randomly select a set of words
5. for each selected word randomly select target class
6. compute the new train set perplexity PP1
7. if (PP1 < PP)
 - keep words in new classes and PP:=PP1
 - else keep words in old classes
8. goto step 3
- end

The main bottleneck for a clustering algorithm is time complexity. We developed a parallelized version of the algorithm in order to speed it up. Using random selection, we achieved a 3.7% improvement in perplexity when comparing the results with the basic clustering algorithm, which replaces words systematically.

Having V words in the vocabulary and clustered into C classes, the space complexity of the class-based bigram language model is $O(C^2 + V)$, in contrast to space complexity $O(V^2)$ of the word-based language model. Using classes, we can enlarge the vocabulary of words by keeping the language model's size small, but this does not solve the problem of OOV words. On the other hand, most speech recognizers use only word-based models. In such cases, class-based models must be converted into word-based ones, which considerably increases the size.

Language Models of Slovenian Language Based on Data-Driven Sub-Word Units

Slovenian words often have many morphological units in common. Two constituent parts can be determined when a highly simplified model of a word is examined: a stem, which can be thought of as responsible for the nuclear meaning of a word, and an ending, which determines the grammatical features. Not all words can be decomposed into stem and ending. In this case an empty ending is used.

In (Sepesy Maučec, Kačič & Horvat, 2004) we showed that it makes sense to model the semantic and grammatical features of words separately:

$$P(w_i | h_i) = P(s_i e_i | h_i) = P(s_i | h_i^*) P(e_i | h_i^{**})$$

w_i is decomposed into a stem s_i and an ending e_i . h denotes previously observed units in the prediction of a stem and an ending.

The prediction of a stem was exposed to topic adaptation. It was presumed that the language in the target environment (where final application would be used) is topically homogeneous. A general language model was tuned to the specific topic by using data at three semantic levels. The first level corresponds to the general language, characterised by the whole corpus. The second level corresponds to the language

characterised by a subset of similar documents. The third level represents a finer level of language topic similarity.

By considering the lengths of histories in predictions, we investigated the following trigram model:

$$P(w_i | w_{i-2} w_{i-1}) =$$

$$P(s_i | s_{i-2} s_{i-1}) \cdot (\lambda P(e_i | e_{i-2} e_{i-1}) + (1 - \lambda) P(e_i | s_i))$$

Prediction of the stem is based on knowledge of the two preceding stems. Prediction of the ending is based on the knowledge of the two preceding endings, and the current stem. In our experiments, the best results were obtained when $\lambda = 0.1$ because a relatively small set of endings can be appended to a particular stem. Some information about word-ending is also contained in the endings of neighbouring words.

The model presupposes a decomposed training corpus. In (Sepesy Maučec, Rotovnik, & Zemljak Jontes, 2003) we used a simple decomposition scheme, based on a preselected set of endings and the longest-match principle. A set of endings was automatically generated over three steps. First, a list was created of all words written in reversed character order. Words were arranged in alphabetical order; thus, words sharing a common ending appear together on the list. The initial characters of adjacent words in the list are compared in order to find a match. Two restrictions were used to avoid over-stemming: the remaining stem should be of a predefined minimum length and the first character of a match must be a vowel. Words should be decomposed at consonant-vowel pair because consonants carry more information about the meaning of word than vowels.

We further improved the decomposition of words in an iterative manner. We searched for the decomposition, which yields the maximized log-likelihood of the training corpus, computed based on sub-word trigrams. The pseudocode of the algorithm is:

1. Collect word bigram counts in train set
2. Set up the initial decomposition
3. Compute the initial log-likelihood of the train set LL
4. while (not stopping criterion is met) do begin
5. randomly select a set of words
6. for each selected word randomly set the new stem-ending boundary
7. compute the new log-likelihood of the train set LL1
8. if (LL1 > LL)

accept new decompositions and LL:=LL1

else keep old decompositions

9. goto step 4

end

The choice of initial decomposition is very important, because final decompositions are only guaranteed to be locally optimal. The initial decomposition was set at the decomposition proposed in (Sepesy Maučec et al., 2003). The stopping criterion was a predefined number of iterations.

Experiments have been performed using a newspaper corpus named 'Večer'. The size of the corpus was 85M words (734k distinct words). 14M word bigram counts were collected from the corpus. After initialization, we had 267k distinct sub-words (264k stems and 3k endings) and the initial sub-word perplexity was 361. After 10,000 iterations the number of distinct sub-units increased to 497k (417k stems and 80k endings) but sub-word perplexity decreased to 291. Data-driven decompositions obtained by this algorithm have already been tested in speech recognition experiments (Rotovnik, Sepesy Maučec & Kačič, 2006). The error rate decreased by 6.3% when compared with the results of speech recognition using word-based models.

FUTURE TRENDS

A lot of work has been done on modelling highly inflective languages but there still exists a lack of knowledge on how to model them 'most effectively'. As an extension of the conventional n -gram language model, a factored language model has been proposed and tested on Arabic (Bilmes & Kirchhoff, 2003). This factored form could also be useful for other highly inflective languages, because it combines information of different types in one general model. To our knowledge, factored language models have not been widely studied on other highly inflective languages yet, except for Arabic and, more recently, Estonian (Alumae, 2006).

CONCLUSION

This chapter gives an overview of applied methods when modelling highly inflective languages. Considering the characteristics of highly inflective languages we exposed models of two types: class-based and

sub-word based. The motivation behind both of them is data-sparsity reduction.

The main idea of class-based models is to reduce the number of free parameters by clustering words into classes. It is interesting that data-driven classes outperformed linguistic classes in many research experiments.

Sub-word based models reduce the size of the vocabulary by splitting words into smaller units and storing these sub-word units (instead of words) in the vocabulary. Data-driven methods to split words into sub-words surpassed grammatical decompositions for many languages.

The reported experiments regarding the use of these types of models (especially in combination with standard word-based) show an overall reduction of errors in the target applications. We draw the same conclusions from our experiments on the Slovenian language. A promising direction for further work is seen in the factored language model.

KEY TERMS

Corpus: A large collection of texts, usually in electronic form. The corpus has greater value if it is tokenized (segmented into sentences, words etc.) and linguistically annotated (for example POS-tagged and lemmatized).

Inflective Language: A language characterized by the use of inflections. Inflection is the modification of a word in order to reflect grammatical information, such as gender, number, person etc.

Language Model: A description of language. In statistical language modelling it is a set of probability estimates.

n-Gram Model: A model, based on the statistical properties of *n*-grams. *N*-gram model predicts the *i*-th unit based on the knowledge of *n-1* previous units. In *n*-gram modelling the assumption is made, that each unit depends only on *n-1* previously observed units. This is the main deficiency of *n*-gram modelling, because it has been shown that the range of dependencies is significantly longer.

Out-Of-Vocabulary Rate: Number of unknown words in a new sample of language (it is called a test set), usually expressed in percentage.

Perplexity: A measure of a language model's quality. It can be interpreted as the geometric mean of the branch out factor of the language model. A language model with perplexity *X* has the same difficulty as an imaginary language in which every word can be followed by *X* different words with equal probability.

Sub-Word Unit: Modelling unit smaller than a word. Sub-word units are usually morphemes, stems and endings, roots, etc.

Unknown Word: Vocabularies are typically fixed to be tens of thousands of words. All words not in the vocabulary are mapped to a single distinguished word, usually called the unknown word.

Vocabulary: A set of words (or other units) being modelled. The same vocabulary is used by the language model and the target application.

Statistical Simulations on Perceptron-Based Adders

Hans Kristian Otnes Berge

University of Oslo, Norway

INTRODUCTION

In this article we compare a number of full-adder (1-bit addition) cells regarding minimum supply voltage and yield, when taking statistical simulations into account. According to the ITRS Roadmap two of the most important challenges for future nanoelectronics design are reducing *power consumption* and increasing *manufacturability* (ITRS, 2005).

We use subthreshold CMOS, which is regarded by many as the most promising ultra low power circuit technique. It is also shown that a minimum redundancy-factor as low as 2 is sufficient to make circuits maintain full functionality under the presence of defects. This is, to our knowledge, the lowest redundancy reported for comparable circuits, and builds on a method suggested a few years ago (Aunet & Hartmann, 2003).

A standard Full-Adder (FA) and an FA based on perceptrons exploiting the “mirrored gate”, implemented in a standard 90 nm CMOS technology, are shown not to withstand statistical mismatch and process variations for supply voltages below 150 mV. Exploiting a redundancy scheme tolerating “open” faults, with gate-level redundancy and shorted outputs, shows that the same two FAs might produce adequate Sum and Carry outputs at the presence of a defect PMOS for supply voltages above 150 mV, for a redundancy factor of 2 (Aunet & Otnes Berge, 2007).

Two additional perceptrons do not tolerate the process variations, according to simulations. Simulations suggest that the standard FA has the lowest power consumption. Power consumption varies more than an order of magnitude for all subthreshold FAs, due to the statistical variations.

BACKGROUND

The first simple mathematical model of the biological neurons, published by McCulloch and Pitts in 1943, calculates the sign of the weighed sum of inputs. Sometimes such circuits are called threshold logic gates or threshold elements. Perceptrons may be used to implement Neural Networks as well as digital signal processing.

Nanoscale CMOS technology is expected to be used alongside other technologies in the future. A typical chip will fail if even a single transistor or wire on the chip is defective. Reducing the power consumption and making defect tolerant circuits have been pointed out as important issues (Mead, 1990), (ITRS, 2005).

Reducing the power supply voltage is the most direct and dramatic means of reducing the power consumption (Liu & Svensson, 1993), and subthreshold circuits operating with a supply voltage, V_{dd} , less than the absolute value of the inherent threshold voltages, V_t , has been known for decades (Svensson, Meindl, 1972).

For older technologies, where manufacturability including threshold voltage variability, was not such an important issue (ITRS 2005), (Wong, Mittal, Cao & Starr, 2004) the minimum supply voltages have often been estimated without mismatch and process variations being taken into account (Liu & Svensson, 1993), (Schrom & Selberherr, 1996). To get more realistic estimates we have simulated and compared 4 different topologies for 1-bit addition under statistical variations in the process and matching properties.

MAIN FOCUS OF THE CHAPTER

MOS Transistors in Subthreshold

For an NMOS transistor in subthreshold we have (Andreou, Boahen, Pouliquen, Pavasovic, Jenkins & Strohhahn, 1991):

$$I_{ds,n} = I_0 e^{\frac{\kappa V_{gs}}{V_t}} e^{(1-\kappa)\frac{V_{bs}}{V_t}} \left(1 - e^{-\frac{V_{ds}}{V_t} + \frac{V_{ds}}{V_0}} \right)$$

$I_{ds,n}$ expresses the current from drain to source. I_0 is the zero-bias current where the pre-exponential constants have been absorbed. This includes the channel width (“W”) and the length (“L”) of the MOSFET structure. V_{gs} is the gate-to-source potential, V_{ds} the drain-to-source potential and V_{bs} the substrate-to-source potential.

V_0 is the Early voltage, which is proportional to the channel length. κ gives the effectiveness for which the gate potential is controlling the channel current. It is often approximately 0.7-0.75 (Andreou, Boahen, Pouliquen, Pavasovic, Jenkins & Strohhahn, 1991). The thermal voltage is expressed as $V_t = kT/q$. $V_t = 25.8$ mV at room temperature.

Though equation (1) takes fewer physical effects and nonmonotonous behaviour in certain cases into account, than for example that reported in (Calhoun, Wang & Chandrakasan, 2004), it does provide sufficient insight to make a brief analysis of many subthreshold circuits. A similar equation apply to PMOS transistors, but with opposite polarities.

Experimental Setup for Statistical Simulations of Functionality and Power Consumption for 1-Bit Adders

For statistical (Monte-Carlo) simulations we used a 90 nm standard CMOS process available through CMP (CMP, 2007). Four different Full Adder (“FA”) circuits having their inputs driven by inverters, and themselves driving simple inverters were simulated. This is illustrated in figure 1. In the case of no redundancy and faults the lower FA in figure (1) was not included.

For each circuit, at 8 different supply voltages, 100 Monte-Carlo “runs” were done, each having the eight possible combinations of the three inputs, for a total simulated period (transient simulation) of 400 μ s, as

illustrated in figure 3 for a case after 5 “runs”. This was far from the maximum operational speed of any of the FAs, meaning that the resulting Sum and Carry signals had more than enough time to settle. Each of the 100 runs represented different mismatch and process parameters, and for each run we checked if the circuit was able to produce correct “0” or “1” outputs for all eight input combinations. The yield, shown in figure 4 represents the percentage of the Full Adders (FAs) working for a given supply voltage, out of 100 Monte Carlo “runs”.

Redundancy using short circuited driven nodes (Aunet & Hartmann, 2003) was exploited, duplicating each gate for the three FAs based on threshold gates (figure 2). For the other FA only the driven nodes prior to the inverters preceeding the S and C nodes were shorted. A total of 4 PMOS transistors were removed from the 4 FAs (one for each FA), so that each FA missed one PMOS in one of it’s threshold gates. This means that each FA in figure 1 had exactly $(2N - 1)$ the number of transistors, N , when compared to the previous case with no redundancy.

The average power consumption for the eight input combinations was also calculated. Each of the four circuits perceptrons, with no redundancy, was tested for 8 different supply voltages.

The missing transistor was in the lowermost “min3” gate (figure 2). For the mirrored gate the missing PMOS was the one having the Z input. For the stacked gate as well as the ijenn gate the missing PMOS was the one between the two other PMOS transistors, referred to figure 2.

For the FA in the upper left corner of figure 2 a PMOS with it’s gate connected to the C_{in} input was the one that was removed. Regarding the rest of the setup it was identical to the one in the previous subsection, describing the case without redundancy.

The FAs put to test were a standard CMOS Full Adder containing 28 transistors (upper, left, in figure 2), while the three others were based on the topology in the upper, right, corner of figure 2. They were based on, from left to right in figure 2, the “mirrored gate” (Hempel, Prost & Scheinberg, 1974), the “stacked” gate (Aunet, Berg & Beiu, 2005) and the “ijenn” gate (Aunet, Oelmann, Abdalla & Berg, 2004), which are all threshold gates.

Regarding transistor dimensions all gate lengths were 100 nm, and all NMOS widths were 220 nm. The standard FA and the “stacked” FA had widths of

all PMOS equal to 400 nm, while the “ijcnn FA” and the “mirrored FA” had PMOS widths of 550 nm and 650 nm, respectively. Buffers, made from two inverters, were inserted on the Sum nodes as well as between the two uppermost threshold gates (“min3”) in figure 2.

Results

The percentage of FA circuits that produced correct logic levels for the Sum and Carry signals, under different conditions, are shown in figure 4. It is clear that the standard CMOS FA and the one based on the mirrored gate gives a larger percentage for a given supply voltage when compared to the FAs based on the two other threshold gates.

Power consumption as a function of supply voltage is shown in figure 5, for the basic circuits without any defect transistors or redundancy.

DISCUSSION

The standard Full Adder, and the threshold gate based topology (upper right corner in figure 2) exploiting the mirrored gate, both need supply voltages of at least 150 mV to tolerate mismatch and process variations, according to our simulations. This may be seen to the left in figure 4. The threshold gates “ijcnn” and “stacked” does not tolerate statistical variations like the two previously mentioned solutions, at least not when there are no redundancy and relatively small

Figure 1. Experimental setup for statistical simulation of 1-bit adder

Figure 2. Schematics for the four 1-bit adders (Full Adders). The standard CMOS version is in the upper left corner, while a topology based on perceptrons and inverters is shown in the upper right corner.

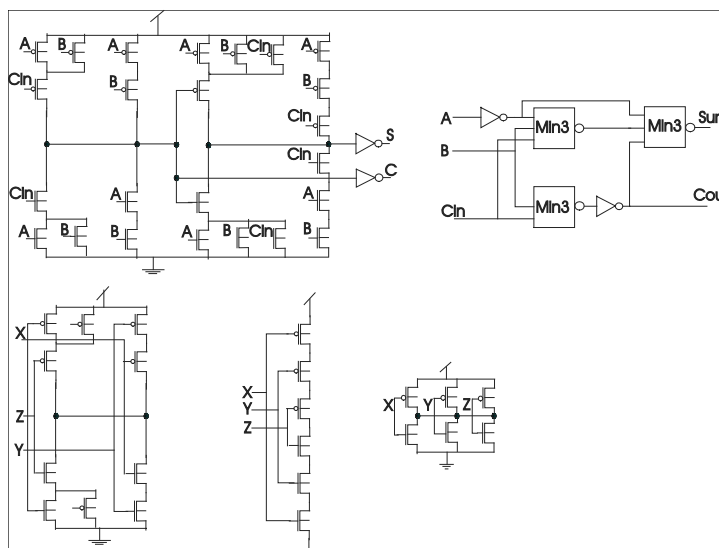

Figure 3. Sum and carry as a function of X , Y and Z inputs for 5 runs

transistors are used. Larger transistors should improve the matching properties and make the circuits less vulnerable to statistical variations in production, as the spread in for example the inherent threshold voltages is inversely proportional to the square root of the product of the widths and lengths of the MOSFETs (Croon, Decoutere, Sansen & Maes, 2004): $\delta(V_T) = A_0(V_T) / \text{Sqrt}(WL)$.

The mirrored threshold gate was adopted for sub-threshold operation and defect-/fault-tolerance using shorted outputs (Aunet & Hartmann, 2003) in (Beiu, Aunet, Nyathi, Rydberg & Djupdal, 2005) and underwent statistical simulations as here, in (Granhaug & Aunet, 2006). Then a redundancy factor of 2 combined with a supply voltage of minimum 175 mV resulted, if a single defect PMOS should be tolerated. In (Granhaug & Aunet, 2006) transistor sizing was slightly different, and the wells of both the PMOS and NMOS transistors

were short circuited, as opposed to our case, where the wells were connected to the rails. For systems of considerable size, implemented in silicon the lowest supply voltage might be 175 mV, reported in (Miyazaki, Kao & Chandrakasan, 2002). Exploiting redundancy, duplicating every gate and tearing one PMOS transistor out from each of the four full-adders gave the results shown to the right in figure 4. The picture is resembling the case to the left, without redundancy, but show some differences. The minimum Vdd to make the standard FA and the one based on the mirrored gate function for all the 100 Monte-Carlo runs was still 150 mV. This is a lower supply voltage than the 175 mV found in (Granhaug & Aunet, 2006). Transistor sizing as well as biasing of wells may have a significant impact on the results, especially in subthreshold, with the many exponential dependencies as shown in equation 1. From figure 4 one can also see that the FAs based on

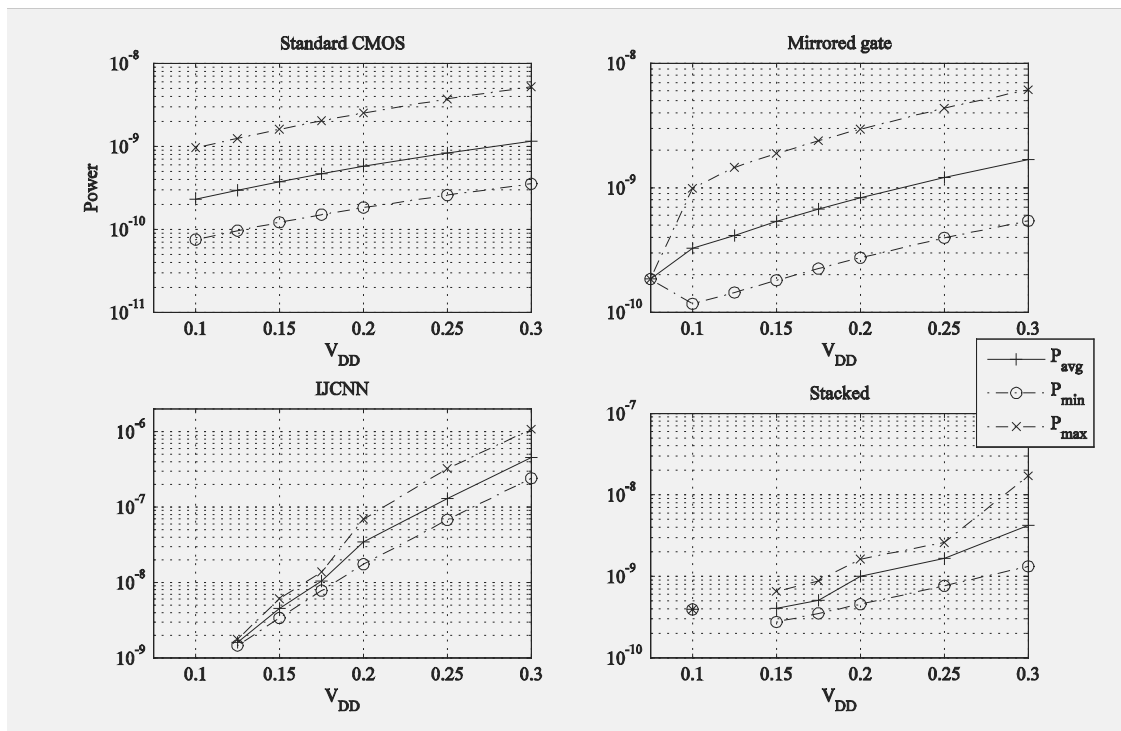

Figure 4. "Yield" from Monte-Carlo simulations of the FAs at different V_{DD} 's ($N=100$)

Figure 5. Power consumption for functional FAs without redundancy

the “mirrored” and the “ijcnn” gates often have a higher yield for a given supply voltage when introducing redundancy and a defect transistor, when compared to the case without redundancy and any defect. The FA based on the “mirrored” gate was the most robust one when there was a defect transistor, giving the highest yield for low supply voltages, according to simulations in figure 4. More simulations, including other defects and additional redundancy could be interesting for future research.

Removing single transistors simulates certain “open” faults in the redundant units, and the scheme using shorted outputs (Aunet & Hartmann, 2003), used in for example (Beiu, Aunet, Nyathi, Rydberg & Djupdal, 2005), (Granhaug & Aunet, 2006) but may not withstand “close” faults like outputs of redundant units shorted to one of the supply rails. A method tolerating such defects as well is presented in (Schmid & Leblebici, 2003). No single technique is enough for tolerating all fault mechanisms in nanoscale circuits and systems, it is concluded in (Lehtonen, Plosila & Isoaho, 2005), so combinations of several methods are needed, depending on the specific design and the proneness to different sources of defects (Lehtonen, Plosila & Isoaho, 2005).

The average, maximum and minimum power consumption in the cases where the FAs were able to produce correct logic outputs are shown in figure 5. The standard CMOS FA shows the lowest average power consumption when the supply voltage is above 150 mV, which is when two of the FAs give a “yield” of 100 percent, according to our results. The FA based on the “mirrored” gate shows a slightly higher power consumption, while the FA based on the “ijcnn” gate displays a power consumption up to orders of magnitude above the others, and increasingly so for the relatively higher supply voltages. Even the FAs showing a relatively high tolerance to mismatch and process variations have current levels ranging over more than an order of magnitude, or a factor 10 x, for a given supply voltage. Power consumption for a given supply voltage is expected to increase linearly with the redundancy factor.

The realism in simulations is limited, especially for nanoscale CMOS (Nassif, 2006). So, layout techniques for high matching, including dummy structures, might lead to different results than those presented here.

FUTURE TRENDS

The assumption that a system is composed largely of correctly functioning units is no longer true in emerging nanoelectronics, and reducing the overall power consumption is also among the grand challenges for future nanoelectronics. The low fan-in perceptrons, also called *voters*, or *minority gates*, might be very useful candidates for future nanoelectronics, which has been recently stated (Beiu & Ibrahim, 2007). Defect tolerant subthreshold perceptron circuits exploiting majority gates, as presented here, may thus be useful building blocks for the future.

CONCLUSION

Statistical Monte-Carlo simulations have been performed on 4 Full Adder circuits. For each FA 100 Monte-Carlo runs were done at 8 different subthreshold supply voltages, and the percentage of the runs providing appropriate logic levels for Sum and Carry outputs was calculated. A “yield” of 100 percent meant that a certain FA would tolerate all simulated combinations of statistical variations. The circuits able to reach this limit were a standard FA and an FA based on the “mirrored” threshold gate, both needing a supply voltage, V_{dd} , above at least 150 mV to guarantee functionality under mismatch and process variations.

When exploiting redundancy and shorting outputs (Aunet & Hartmann, 2003), a supply voltage less than 150 mV is not enough to tolerate the statistical variations when a PMOS is removed from the schematics and a redundancy factor of 2 is used. The standard and mirrored-based FAs are still working for a supply voltage above 150 mV for one defect MOSFET. Power consumption varies by approximately 1 order of magnitude, for all the 4 simulated FAs in subthreshold, with the standard FA having the lowest power consumption at useful supply voltages tolerating large statistical variations.

KEY TERMS

Full Adder: Circuit that produces the binary sum and carry when adding two binary numbers.

Minority-3 Gate: A minority 3 gate outputs a logic “0” signal if, and only if, 2 or 3 out of it’s three binary inputs are “1”.

Mismatch: Ideally identically constructed elements on an integrated circuits have a mismatch when they differ in their physical properties after production of the chip.

Monte Carlo Simulations: Computer simulations basing the results on statistical distribution of parameters.

Nanoscale CMOS: CMOS technologies where dimensions smaller than 100 nm is critical to the functioning of the produced chip.

Neuron: Electrically excitable cells in the nervous system that process and transmit information.

Parameter Variations: Parameters describing physical traits of integrated circuits may have variations due to mismatch, for example the threshold voltages of transistors.

Perceptron: Type of artificial (feedforward) Neural Network.§

Yield: In this paper the term yield refers to the ratio of functional circuits to the total number of simulated circuits. Often yield refers to the ratio of functional chips to the total number of manufactured chips.

Stochastic Approximation Monte Carlo for MLP Learning

Faming Liang

Texas A&M University, USA

INTRODUCTION

Over the past several decades, multilayer perceptrons (MLPs) have achieved increased popularity among scientists, engineers, and other professionals as tools for knowledge representation. Unfortunately, there is no a universal architecture which is suitable for all problems. Even with the correct architecture, frustrating problems of connection weights training still remain due to the rugged nature of the energy landscape of MLPs. The energy function often refers to the sum-of-square error function for conventional MLPs and the negative log-posterior density function for Bayesian MLPs.

This article presents a Monte Carlo method that can be used for MLP learning. The main focus is on how to apply the method to train connection weights for MLPs. How to apply the method to choose the optimal architecture and to make predictions for future values will also be discussed, but within the Bayesian framework.

BACKGROUND

As known by many researchers, the energy landscape of an MLP is often rugged. The gradient-based training algorithms, such as back-propagation (Rumelhart et al., 1986), conjugate gradient, Newton's method, and the BFGS algorithm (Broyden, 1970, Fletcher, 1970, Goldfarb, 1970, Shanno, 1970), tend to converge to a local minimum near the starting point, rendering the training data learned insufficiently. To reduce the chance of converging to local minima, a number of variants of these algorithms have been proposed based on the idea of perturbation (von Lehmen et al., 1988, Tang et al., 2003 and references therein). In practice, the effects of these perturbations are usually limited, which only delay the learning process converging to local minima a reasonable number of iterations (Ingman & Merlis, 1991).

To avoid the local-trap problem, simulated annealing (SA) (Kirkpatrick et al., 1983) has been employed by some authors to train neural networks. Amato et al. (1991) and Owen & Abunawass (1993) show that for complex learning tasks, SA has a better chance to converge to a global minimum than have the gradient-based algorithms. Geman & Geman (1984) show that the global minimum can be reached by SA with probability 1 if the temperature decreases at a logarithmic rate of $O(1/\log t)$, where t denotes the number of iterations. In practice, however, no one can afford to have such a slow cooling schedule. Most frequently, people use a linearly or geometrically decreasing cooling schedule, which can no longer guarantee the global energy minimum to be reached (Holley, et al., 1989).

Other stochastic algorithms that have been used in MLP training include the genetic algorithm (Goldberg, 1989) and Markov chain Monte Carlo (MCMC). Although the genetic algorithm works well for some problems, see, e.g., van Rooij et al. (1996), there is no theory to support its convergence to global minima. MCMC algorithms are mainly used for Bayesian MLPs (MacKay, 1992a, Neal, 1996, Muller & Insua, 1998, de Freitas et al., 2000, Liang, 2003, 2005a, 2005b), which will be discussed later.

MAIN FOCUS OF THE CHAPTER

This article presents how the stochastic approximation Monte Carlo (SAMC) (Liang et al., 2007) algorithm can be used for MLP learning, including training, prediction and architecture selection.

A Brief Review for the SAMC Algorithm

Suppose that we are working with the Boltzmann distribution,

$$p(x) = \frac{1}{Z} e^{-U(x)/\tau}, \quad x \in \Omega, \quad (1)$$

where Z is the normalizing constant, $U(x)$ is the energy function, τ is the temperature, and Ω is the sample space. Without loss of generality, we assume that Ω is compact. For MLPs, x denotes the vector of connection weights, and Ω can be restricted to a hyper-rectangle $[-B_\Omega, B_\Omega]^{\dim(\Omega)}$, where B_Ω is a large number such that Ω includes at least a global minimum of $U(x)$. Furthermore, we assume that the sample space can be partitioned according to the energy function into m disjoint subregions: $E_1 = \{x: U(x) \leq u_1\}$, $E_2 = \{x: u_1 < U(x) \leq u_2\}$, ..., $E_{m-1} = \{x: u_{m-2} < U(x) \leq u_{m-1}\}$, and $E_m = \{x: U(x) > u_{m-1}\}$, where u_1, \dots, u_{m-1} are pre-specified real numbers. SAMC seeks to draw samples from each subregion with a pre-specified frequency. If this goal can be achieved, then the local-trap problem can be avoided successfully. Let x_{t+1} denote a sample simulated from the distribution

$$p_{\theta_t}(x) \propto \sum_{i=1}^m \frac{\Psi(x)}{e^{\theta_{ti}}} I(x \in E_i) \quad (2)$$

using the Metropolis-Hastings (MH) algorithm (Metropolis et al., 1953, Hastings, 1970), where $\Psi(x) = e^{-U(x)/\tau}$ and $\theta_t = (\theta_{t1}, \dots, \theta_{tm})$ is an m -vector in a space Θ . For simplicity, we assume that Θ is compact, e.g., $\Theta = [-B_\Theta, B_\Theta]^{\dim(\Theta)}$ with B_Θ being a large number. Since adding to or subtracting from θ_t a constant will not change $p_{\theta_t}(x)$, θ_t can be kept in the compact set in simulations by adjusting with an additive constant. Let the proposal distribution, $q(x, y)$, of the MH moves satisfy the minorisation condition (Mengersen & Tweedie, 1996), i.e.,

$$\sup_{\theta \in \Omega} \sup_{x, y \in \Omega} \frac{p_\theta(y)}{q(x, y)} < \infty \quad (3)$$

Since Ω is compact, a sufficient design for the minorisation condition is to choose $q(x, y)$ as a global proposal distribution. A proposal distribution is said global if $q(x, y) > 0$ for all $x, y \in \Omega$. For MLPs, $q(x, y)$ can be chosen as a random walk Gaussian proposal, $y \sim N(x, \sigma^2 I)$, where I is an identity matrix and σ^2 is calibrated such that the MH moves have a desired acceptance rate. As discussed later, restricting the proposal distribution to be global ensures the convergence of the annealing SAMC algorithm to the global energy minima.

Let $\{\gamma_t\}$ be a positive non-decreasing sequence satisfying the conditions:

$$\begin{aligned} \text{i.} \quad & \sum_{t=0}^{\infty} \gamma_t = \infty, \\ \text{ii.} \quad & \sum_{t=0}^{\infty} \gamma_t^\delta < \infty \end{aligned}$$

for some $\delta \in (1, 2)$. For example, one can set

$$\gamma_t = \left(\frac{t_0}{\max(t_0, t)} \right)^\eta \quad (4)$$

for some values of $t_0 > 1$ and

$$\eta \in \left(\frac{1}{2}, 1 \right).$$

A large value of t_0 will allow the sampler to reach all subregions very quickly, even in the presence of multiple local minima. Let $\pi = (\pi_1, \dots, \pi_m)$ be an m -vector with $0 < \pi_i < 1$ and

$$\sum_{i=1}^m \pi_i = 1,$$

which defines a desired sampling frequency distribution on the subregions. With the above notations, an iteration of SAMC can be described as follows.

SAMC Algorithm

- a. Generate $x_{t+1} \sim K_{\theta_t}(x_t, \cdot)$ with a single MH step:
 1. Generate y according to the proposal distribution $q(x_t, y)$.
 2. Calculate the ratio

$$r = e^{\theta_{tJ(x_t)} - \theta_{tJ(y)}} \frac{\Psi(y)}{\Psi(x_t)} \frac{q(y, x_t)}{q(x_t, y)},$$

where $J(x)$ denote the index of the subregion that the sample x belongs to.

3. Accept the proposal with probability $\min(1, r)$. If it is accepted, set $x_{t+1} = y$; otherwise, set $x_{t+1} = x_t$.

- b. Set $\theta^* = \theta_t + \gamma_t (e_{t+1} - \pi)$, where γ_t is called the gain factor, $e_{t+1} = (e_{t+1,1}, \dots, e_{t+1,m})$, and $e_{t+1,i} = 1$ if $x_{t+1} \in E_i$ and 0 otherwise.
- c. If $\theta^* \in \Theta$, set $\theta_{t+1} = \theta^*$; otherwise, set $\theta_{t+1} = \theta^* + c^*$, where c^* is a constant vector and is chosen such that $\theta^* + c^* \in \Theta$. The existence of c^* is obvious, since B_Θ has been set to a large number and it is reasonable to assume that $\max_{i=1}^m \theta_i^* - \min_{i=1}^m \theta_i^* \ll B_\Theta$ holds at each iteration.

A remarkable feature of SAMC is its self-adjusting mechanism. If a proposal is rejected, the weight of the subregion that the current sample belongs to will be adjusted to a larger value, and thus a proposal of jumping out from the current subregion will be less likely rejected in the next iteration. This mechanism effectively prevents the system from getting trapped in local minima. This is very important for MLP training as its energy landscape is often rugged.

SAMC falls into the category of stochastic approximation algorithms (Robbins & Monro, 1951, Andrieu et al., 2005 and references therein). The convergence of SAMC can be extended from a theorem presented in Liang et al. (2007). Under mild conditions and as $t \rightarrow \infty$,

$$\theta_{it} \rightarrow \begin{cases} C + \log \left(\int_{E_i} \psi(x) dx \right) - \log(\pi_i + \zeta), & E_i \neq \emptyset, \\ -\infty, & E_i = \emptyset, \end{cases} \quad (5)$$

where

$$\zeta = \sum_{j \in \{i: E_i = \emptyset\}} \pi_j / (m - m_0)$$

and $m_0 = \#\{i : E_i = \emptyset\}$ is the number of empty subregions, and C is an arbitrary constant. A subregion E_i is said to be empty if

$$\int_{E_i} \psi(x) dx = 0.$$

In SAMC, the sample space partition can be made blindly by simply specifying some values u_1, \dots, u_{m-1} . This may result in some empty subregions. The constant C can be determined by imposing a constraint on θ_i , say,

$$\sum_{i=1}^m e^{\theta_i}$$

is equal to a known number. In addition, Liang (2007) shows that θ_i can converge in the form L_2 at a rate of $O(1/t)$. Let $\pi_{it} = P(x_t \in E_i)$ be the probability of sampling from the subregion E_i at iteration t . Equation implies that as $t \rightarrow \infty$, π_{it} will converge to $\pi_i + \zeta$ if $E_i \neq \emptyset$ and 0 otherwise. This further implies that as the number of iterations goes to infinity, SAMC can approximately draw samples from each of the subregions with a pre-specified probability. With an appropriate specification of π , sampling can be biased to the low energy regions to increase the chance of finding the global minimum.

Annealing SAMC for MLP Learning

In theory, SAMC is able to find the global energy minima if the run is long enough. However, due to the broadness of the sample space, the process may be slow even when sampling is biased to low energy subregions. To accelerate the search process, one can iteratively shrink the sample space in simulations. As argued below, this modification preserves the theoretical property of SAMC when a global proposal distribution is used.

Suppose that the subregions E_1, \dots, E_m have been arranged in ascending order by energy; that is, if $i < j$ then $U(x) < U(y)$ for any $x \in E_i$ and $y \in E_j$. Let $\kappa(u)$ denote the index of the subregion that a sample x with energy u belongs to. Let Ω_t denote the sample space at iteration t . Annealing SAMC, which will be abbreviated as ASAMC hereafter, starts with

$$\Omega_1 = \bigcup_{i=1}^m E_i,$$

and then iteratively sets

$$\Omega_t = \bigcup_{i=1}^{\kappa(U_{\min}^t + \Delta)} E_i \quad (6)$$

where U_{\min}^t is the minimum energy value obtained by iteration t , $\Delta > 0$ is a user specified parameter. The sample space Ω_t shrinks iteration by iteration. In this sense, the modified algorithm is called ASAMC.

Since the proposal distribution is global, the convergence property of SAMC still holds for ASAMC on the limiting space $\Omega_\infty = \lim_{t \rightarrow \infty} \Omega_t$, although Ω_∞ may contain some separated regions. The existence of Ω_∞ is true due to the monotonicity of the sequence $\Omega_1 \supseteq$

$\Omega_2 \supseteq \dots$. It follows from Scheffe's theorem (Scheffe, 1947) that as $t \rightarrow \infty$, x_t will converge in distribution to a random variable with density

$$p_\theta(x) \propto \sum_{i=1}^{\kappa(u_{\min} + \Delta)} \frac{(\pi_i + \zeta) \Psi(x)}{\int_{E_i} \Psi(x) dx} I(x \in E_i), \quad (7)$$

where u_{\min} denotes the global minimum of the energy function $U(x)$. Again, as in SAMC, the convergence can be attained in the L_2 form at a rate of $O(1/t)$. If we let Δ go to zero, then the ASAMC samples will converge in distribution to the global minima of $U(x)$.

For an effective implementation of ASAMC, several issues need to be considered.

Sample space partitioning. Since within the same subregion, ASAMC is reduced to sampling from the unnormalized density $\Psi(x)$, we suggest that the maximum energy difference in each subregion should be bounded by a reasonable number, say, 2τ , to ensure that the local Metropolis-Hastings moves within the same subregion have a reasonable acceptance rate.

Choice of Δ . The performance of ASAMC depends on the value of Δ to some extent. If Δ is too large, ASAMC may take a long time to locate the global minimum due to the broadness of the sample space. If Δ is too small, ASAMC may also take a long time to locate the global minimum. In this case, the sample space may contain only a few separated regions, and the most proposed transitions will be rejected. In our experience, a value of Δ between 5 and 10 works well for most MLP problems.

Desired sampling distribution. The choice of π is not critical to the efficiency of ASAMC, as in which the sample space has been shrunked with iterations. On the contrary, in SAMC, π should be chosen carefully to bias sampling to low energy regions to improve ergodicity of the simulation.

Gain factor. To estimate the integrals

$$\int_{E_1} \Psi(x) dx, \dots, \int_{E_m} \Psi(x) dx$$

accurately, γ_t should be very close to 0 at the end of simulations. Otherwise, the resulting estimates may have a large variation. The decreasing speed of γ_t can be controlled by t_0 and η . In practice, we often fix $\eta = 1$ and vary the value of t_0 according to the complexity of the problem. The more complex the problem is, the larger value of t_0 one should choose.

Convergence diagnostic. A formal diagnostic for the convergence of ASAMC should base on multiple runs. A rough diagnostic for a single run can be done by comparing the observed sampling frequencies and the desired sampling frequencies of different subregions. If they match with each other very well, we may regard the run converged. Otherwise, one may re-run the algorithm with a larger number of iterations or a larger value of t_0 .

ASAMC has been compared in Liang (2007) with simulated annealing, SAMC, and the BFGS algorithm on a number of examples, including the famous N-parity and two-spiral problems. The numerical results for the two-spiral problem are re-presented in Table 1 and

Table 1. Comparison of ASAMC, SAMC, SA and BFGS for the two-spiral problem. Notations: let z_i denote the minimum energy value obtained in the i th run. "Mean" = $\sum_{i=1}^{20} z_i / 20$, "SD" is the standard deviation of "mean", "Minimum" = $\min_{i=1}^{20} z_i$, "Maximum" = $\max_{i=1}^{20} z_i$, "Proportion" = $\#\{i : z_i \leq 0.2\}$, "Iteration" is the average number of iterations performed in each run, and "Time" is the average CPU time cost by each run.

| Algorithm | Mean | SD | Minimum | Maximum | Proportion | Iteration(10^6) | Time |
|-----------|--------|-------|---------|---------|------------|---------------------|------|
| ASAMC | 0.620 | 0.191 | 0.187 | 3.23 | 15 | 7.1 | 94m |
| SAMC | 2.727 | 0.208 | 1.092 | 4.09 | 0 | 10.0 | 132m |
| SA-1 | 17.845 | 0.706 | 9.020 | 22.06 | 0 | 10.0 | 123m |
| SA-2 | 6.433 | 0.450 | 3.030 | 11.02 | 0 | 10.0 | 123m |
| BFGS | 15.500 | 0.899 | 10.00 | 24.00 | 0 | --- | 3s |

Figure 1. Classification maps learned for the two-spiral problem by ASAMC with a MLP of 30 hidden units. The black and white points show the training data for the two different spirals, respectively. (a) Classification map learned in a run. (b) Classification map averaged over 20 run.

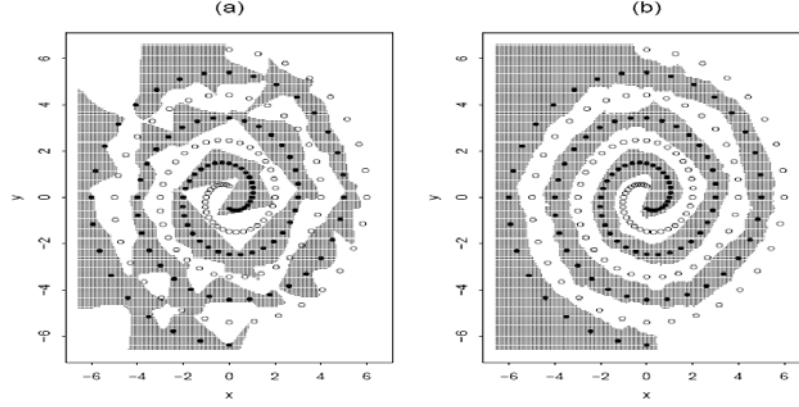

Figure 1. Refer to Liang (2007) for the settings of the respective algorithms. The results for the other examples are similar. In summary, ASAMC outperforms the other algorithms in both training and test errors. Like other stochastic algorithms, ASAMC requires longer training time than do the gradient-based algorithms. It provides, however, an efficient approach to train MLPs for which the energy landscape is rugged.

Bayesian MLP Learning

SAMC can also be used for training Bayesian MLPs. Let $\Psi(x)$ denote the posterior density of a MLP (up to a normalizing constant), and $\hat{g}_i = \lim_{t \rightarrow \infty} e^{\theta_{it}}$. Thus, the following density

$$\widehat{p}(x) \propto \sum_{i=1}^m \frac{\Psi(x)}{\hat{g}_i} I(x \in E_i) \quad (8)$$

can work as a trial density for sampling from $\Psi(x)$. As a trial density, it possesses two nice properties. First, the importance weight is bounded above by $\max_i \hat{g}_i$, assuming that \hat{g}_i has been normalized by an additional constraint, e.g.,

$$\sum_{i=1}^m \hat{g}_i$$

is a known constant. Second, sampling from $\widehat{p}(x)$ will lead to a random walk in the space of nonempty sub-

regions if we regard each subregion as a point. Hence, the whole sample space can be well explored.

Suppose that important samples $(x_1, w_1), \dots, (x_n, w_n)$ have been drawn from using a MCMC sampler, where w_i denotes the importance weight of x_i . Let $f(z|x)$ denote the output of the MLP with input z . For a new input z_0 , the Bayesian point prediction is then

$$\widehat{f}(z_0) = \frac{\sum_{i=1}^n w_i f(z_0 | x_i)}{\sum_{i=1}^n w_i} \quad (9)$$

Evidence Evaluation for Bayesian MLPs

In addition to MLP learning, SAMC also provides a convenient way for evaluating evidence of Bayesian MLPs. As pointed out by MacKay (1992b), the Bayesian evidence can be used as a guideline of architecture selection for Bayesian MLPs. Let $f(D|x)$ denote the likelihood function of a given MLP model, and let $l(x)$ denote the prior density imposed on x . As before, we suppose that Ω has been restricted to a compact set. Define the function

$$\Psi(x, k) = \begin{cases} f(D|x)l(x), & k=1 \\ 1/|\Omega|, & k=0 \end{cases} \quad (10)$$

on the product space $\Omega \times \{0, 1\}$, where $|\Omega|$ denotes the hypervolume of the space Ω . Partition the product space as follows: $E_0 = \{(x, k) : k=0, x \in \Omega\}$, $E_1 = \{(x, k) : k=$

$1, U(x) \leq u_1\}, \dots, E_m = \{(x, k) : k = 1, U(x) > u_{m-1}\}$. If SAMC is run with this partition, the evidence of the MLP can then be estimated by

$$\widehat{EV} = \frac{\sum_{i=1}^m (\pi_i + \zeta) \widehat{g}_i}{(\pi_0 + \zeta) \widehat{g}_0} g_0, \quad (11)$$

where

$$g_0 = \int_{E_0} \Psi(x, 0) dx,$$

$$\widehat{g}_i = \lim_{t \rightarrow \infty} e^{\theta_i},$$

and $0 < \pi_0 < 1$. We note that $\Psi(x, 0)$ can be any non-negative function with g_0 being analytically available.

FUTURE TRENDS

In the future, we need to carry out a series of comparisons to assess the ability of SAMC in different aspects. For example, we need to compare SAMC with advanced MCMC samplers, such as parallel tempering (Geyer, 1991) and evolutionary Monte Carlo (Liang & Wong, 2001), to assess its ability in Bayesian prediction; and to compare SAMC with the Gaussian approximation method (MacKay, 1992b) to assess its ability in evidence evaluation.

CONCLUSION

This article proposes an innovative method for MLP training, prediction, and architecture selection. The strength of SAMC comes from its self-adjusting mechanism, which enables it to overcome the local-trap problems. Like simulated annealing and genetic algorithms, SAMC avoids the requirement for the gradient information of the objective function. Hence, it can be used as a general optimization, simulation, and integration tool in many other problems, such as combinatorial optimization, model selection, and statistical simulations.

KEY TERMS

Genetic Algorithm: A search heuristic used in computing to find true or approximate solutions to global optimization problems.

Markov Chain Monte Carlo (MCMC): A class of algorithms for sampling from probability distributions by simulating a Markov chain that has the desired distribution as its stationary distribution. The state of the Markov chain after a large number of steps is then used as a sample from the desired distribution.

Metropolis-Hastings Algorithm: A popular MCMC algorithm with the acceptance probability $\{1, [f(y)q(y,x)]/[f(x)q(x,y)]\}$ for a new state y given the current state x , where $f(\cdot)$ is the target distribution and $q(\cdot, \cdot)$ is the proposal distribution.

Model Evidence: The log-marginal likelihood of the data obtained by integrating out the parameters over the space of models. Its value expresses the preference shown by the data for different models.

Multiple Layer Perceptron (MLP): An important class of neural networks, which consists of a set of source nodes that constitute the input layer, one or more layers of computational nodes, and an output layer of computational nodes. The input signal propagates through the network in a forward direction, on a layer-by-layer basis.

Simulated Annealing: A generic probabilistic meta-algorithm used to find true or approximate solutions to global optimization problems.

Stochastic Approximation Algorithm: A probabilistic meta-algorithm suggested by Robbins and Monro (1951) for solutions of regression equations.

INTRODUCTION

An *Artificial Neural Network* (ANN) is a computational structure inspired by the study of biological neural processing. Although neurons are considered as very simple computation units, inside the nervous system, an incredible amount of widely inter-connected neurons can process huge amounts of data working in a parallel fashion. There are many different types of ANNs, from relatively simple to very complex, just as there are many theories on how biological neural processing works. However, execution of ANNs is always a heavy computational task. Important kinds of ANNs are those devoted to pattern recognition such as *Multi-Layer Perceptron* (MLP), *Self-Organizing Maps* (SOM) or *Adaptive Resonance Theory* (ART) classifiers (Haykin, 2007).

Traditional implementations of ANNs used by most of scientists have been developed in high level programming languages, so that they could be executed on common *Personal Computers* (PCs). The main drawback of these implementations is that though neural networks are intrinsically parallel systems, simulations are executed on a *Central Processing Unit* (CPU), a processor designed for the execution of sequential programs on a *Single Instruction Single Data* (SISD) basis. As a result, these heavy programs can take hours or even days to process large input data. For applications that require real-time processing, it

is possible to develop small ad-hoc neural networks on specific hardware like *Field Programmable Gate Arrays* (FPGAs). However, FPGA-based realization of ANNs is somewhat expensive and involves extra design overheads (Zhu & Sutton, 2003).

Using dedicated hardware to do machine learning was typically expensive; results could not be shared with other researchers and hardware became obsolete within a few years. This situation has changed recently with the popularization of *Graphics Processing Units* (GPUs) as low-cost and high-level programmable hardware platforms. GPUs are being increasingly used for speeding up computations in many research fields following a *Stream Processing Model* (Owens, Luebke, Govindaraju, Harris, Krüger, Lefohn & Purcell, 2007).

This article presents a GPU-based parallel implementation of a Fuzzy ART ANN, which can be used both for training and testing processes. Fuzzy ART is an unsupervised neural classifier capable of incremental learning, widely used in a universe of applications as medical sciences, economics and finance, engineering and computer science. CPU-based implementations of Fuzzy ART lack efficiency and cannot be used for testing purposes in real-time applications. The GPU implementation of Fuzzy ART presented in this article speeds up computations more than 30 times with respect to a CPU-based C/C++ development when executed on an NVIDIA 7800 GT GPU.

BACKGROUND

Biological neural networks are able to learn and adapt its structure based on the external or internal information that flows through the network. Most types of ANNs present the problem of *catastrophic forgetting*. Once the network has been trained, if we want it to learn from new inputs, it is necessary to repeat the whole training process from the beginning. Otherwise, the ANN would forget previously acquired knowledge. S. Grossberg developed the *Adaptive Resonance Theory* (ART) to address this problem (Grossberg, 1987). Fuzzy ART is an extension of the original ART 1 system that incorporates computations from *fuzzy set theory* into the ART network, and thus making it possible to learn and recognize both analog and binary input patterns (Carpenter, Grossberg & Rosen, 1991).

GPUs are being considered in many fields of computation and some researchers have made efforts for integrating different kinds of ANNs on the GPU. Most research has been done for implementing *Multi-Layer Perceptron* (MLP) taking advantage of the GPU performance in matrix-matrix products (Rolfes, 2004) (Oh & Jung 2004) (Steinkraus, Simard & Buck 2005). Other researchers have used the GPU for *Self-Organizing Maps* (SOM) with great results (Luo, Liu & Wu, 2005) (Campbell, Berglund & Streit, 2005). Bernhard et al. achieved a speed increase of between 5 and 20 times simulating large networks of *Spiking Neurons* on the GPU (Bernhard & Keriven, 2006). Finally, Martínez-Zarzuela et al. developed a generic *Fuzzy ART ANN* on the GPU achieving a speed up higher than 30 over a CPU (Martínez-Zarzuela, Díaz, Díez & Antón, 2007).

Commodity graphics cards provide a tremendous computational horsepower. NVIDIA's GeForce 7800 GTX GPU is able to sustain 165 GFLOPS against the 25.6 GFLOPS theoretical peak for the SSE units of a dual-core 3.7 GHz Intel Pentium Extreme (Owens, Luebke, Govindaraju, Harris, Krüger, Lefohn & Purcell, 2007). Newest generation of graphics cards, like NVIDIA Geforce 8800 Ultra, or AMD (ATI) Radeon HD 2900 XT, can give a peak performance higher than 500 Gflops and 100 GB/s peak memory bandwidth. Graphics cards manufacturers have recently discovered the field of high performance computing as to be a target market for their products and are providing specific hardware and software to couple with enterprises and researchers heavy computational requirements.

FUZZY ART NEURAL NETWORK STREAM PROCESSING

This article describes a parallel implementation of a Fuzzy ART ANN using a *stream processing model*. In this uniform parallel processing paradigm a series of computations, defined by one function or *kernel*, are made over an ordered set of data or *stream* on a *Single Instruction Multiple Data* (SIMD) basis. The main restriction of the model is also one of the reasons it can provide large increases in performance and a simplified programming model: operations on each stream element are independent, allowing the execution of the kernel on different hardware processing units simultaneously, and avoiding stalls that could occur because of inter-units data sharing.

GPUs used to have two types of programmable processors, namely *vertex* and *fragment* processors. Both kinds of processors were devised to operate on four component vectors, as the basic primitives of 3D computer graphics are 3D vertices in projected space (x, y, z, w) and four component colors (*red, green, blue, alpha*). Both vertex and fragment units could be used to execute a *kernel* over a *stream of data* (*Stream Processing*) and are programmed using *shaders* that can be written using high level languages as Cg (Randima & Kilgard, 2003), GLSL or HLSL. Latest generation of GPUs, like nVIDIA GeForce 8800 GTX, do not include fragment or vertex processors, but unified *Stream Processors* (SPs): generalized floating-point scalar processors capable of operating on vertices, pixels, or any manner of data. These new GPUs can be programmed using CUDA (*Compute Unified Device Architecture*) Toolkit from nVIDIA. CUDA is a promising new software development solution for programming GPUs, simplifying software development by using the standard C language. Before CUDA was launched programming GPUs for *General Purpose* computation (GPGPU) involved translating algorithms into graphics terms (Harris, 2005). Other companies like *Rapidmind* are developing easy-to-program APIs that use just-in-time (JIT) compilers for translating source code into a format that will work on several system's hardware (GPU, Cell or an x86 CPU). Arrays of data can be uploaded from the CPU to the GPU memory and stored in *textures*. RGBA textures can be used to store 4 floating point data per texture unit (*texel*). Data is modified along the *graphics pipeline* and then written to the *frame-buffer* memory or rendered to a

new texture, allowing a direct feedback of the output to the pipeline's entry.

Fuzzy ART Equations

Fuzzy ART systems are comprised of three layers or fields of nodes. First layer receives the input vector denoted by $\vec{I} = (I_1, \dots, I_M)$. Nodes in the output layer represent the active code or category of the input pattern being selected. For each output neuron, a *choice function* $T_j (j : 1 \dots N)$ is defined by:

$$T_j(\vec{I}) = \frac{|\vec{I} \wedge w_j|}{\alpha + |w_j|}, \quad (1)$$

where $w_j = (w_{j1}, \dots, w_{jM})$ denotes associated *Long-term Memory* (LTM) trace, fuzzy MIN operator \wedge is defined by $(p_i \wedge q_i) \equiv \min(p_i, q_i)$ and the norm $|\cdot|$ is defined by

$$|\vec{p}| \equiv \sum_{i=1}^M |p_i|.$$

Category choice is indexed by J , where $T_J = \max(T_j : j = 1 \dots N)$ and system enters in *resonance* if the *match function* meets the *vigilance criterion*:

$$\frac{|\vec{I} \wedge w_J|}{|\vec{I}|} \geq \rho. \quad (2)$$

When this occurs, vector w_j is updated using (3). Otherwise, node J is inhibited making $T_j = 0$. If no node

j is found to meet the vigilance criterion, a new output neuron is committed.

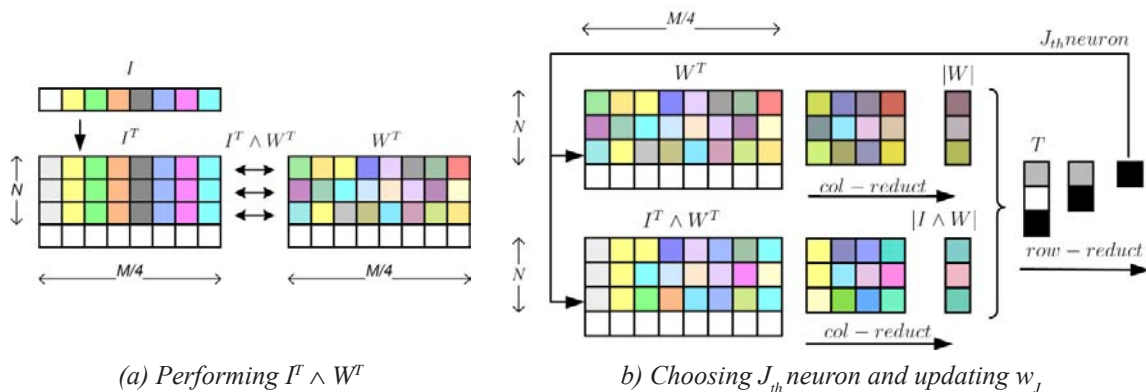

$$w_j^{new} = \beta (\vec{I} \wedge w_j^{old}) + (1 - \beta) w_j^{old} \quad (3)$$

Fuzzy ART Training Process on the GPU

Learning is not a parallel but a sequential process. Different input patterns cannot be learned at the same time, because they would all generate different categories. Optimizing the training process for parallel execution must be done when searching for the category that most resembles the input pattern. Fuzzy ART implementations on the CPU sequentially compute the activity for every output node. Then, a sort operation is made in order to know which neuron is most fired by the input pattern (1). If the category stored in this neuron resembles input pattern (2), its associated weights are updated with the new information (3); otherwise, the next most fired neuron must be analyzed. In a *parallel stream processing* implementation, we can compute the choice function for every output neuron (1) in a parallel fashion. Moreover, we can obtain the match function (2) for every node simultaneously.

In a GPU implementation, weights of every committed neuron w_j are stored as rows in a texture W^T . Input pattern \vec{I} is rendered to every row of a texture I^T with same dimensions as W^T , so that during category choice, it can be compared to every LTM traces at once, as it is shown in Fig. 1a). Global operations over the elements of a *stream of data*, such as calculating its maximum or the sum are tricky to perform in a GPU

Figure 1. Training process of a Fuzzy ART ANN on a GPU

and must be accomplished by doing several render passes. A *ping-pong technique* consists in using the output of a rendering pass as input in the next one. In each pass a local operation is made between neighborhood elements in a texture and the results are written to a smaller texture. After a series of *reductions*, the final result is obtained (Horn, 2005). Calculating the norms $|\tilde{I} \wedge w_j|$ and $|w_j|$ is made using a *column reduction operation* along textures W^T and $I^T \wedge W^T$, as it is shown in Fig 1b).

The use of RGBA textures allows running MIN and SUM operations on 4-component vectors in one clock cycle on every *fragment shader* unit, making the process faster. If dimensions of input patterns are not multiple of 4, unused channels of the RGBA textures must be padded with zeros. Reduced textures are then used to store the activity of each neuron, satisfying the match criteria, on the R channel of a texture T ; the G channel is used to store the category index; the A channel takes the value of 1 in case the match criteria is satisfied and 0 otherwise; finally, channel B can be used for printing the matching rate, which can be very useful for debugging purposes.

The J_{th} neuron is found using a *row reduction operation* over texture T , in which those fragments not satisfying the match criteria are discarded. If the system enters in resonance, the weights of the selected category are updated by rendering into the corresponding sub-region of texture W^T . If not, the new pattern is

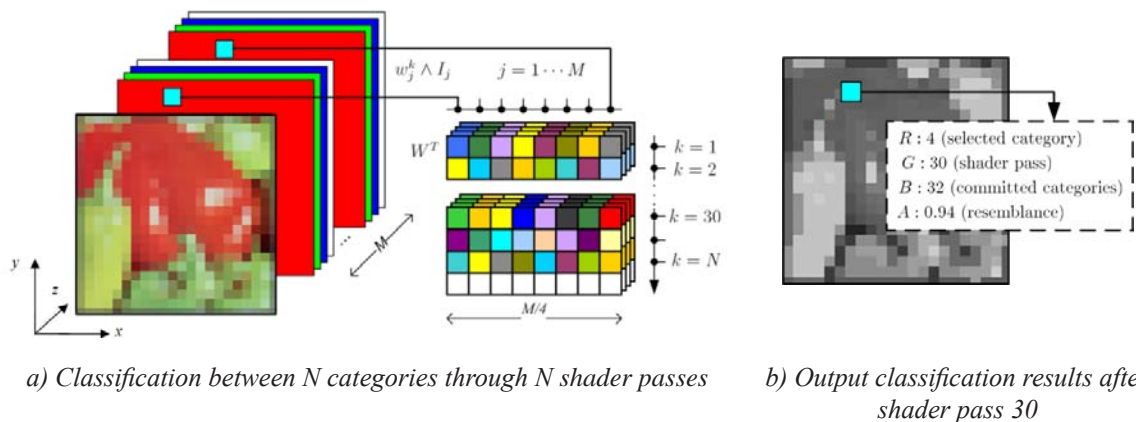

learned by rendering to an unused row of weights in W^T according to equation (3).

Fuzzy ART Testing Process on the GPU

The Fuzzy ART testing algorithm is easier and much more profitable to implement on the GPU. In this process, several input patterns can be categorized in a parallel fashion when learning mode is switched off. The best data configuration takes advantage of every *stream processor* available on the GPU for categorizing each pattern in several *shader passes*. Fig. 2 shows the organization of the data on the GPU. In the proposed system, for every (x,y) coordinate pair on the input data, a pattern is stored along the z direction. A single RGBA texture can store 4 component input vectors, and several RGBA textures can be used to store greater patterns. After N *shader passes*, being N the number of committed categories by the network, an output RGBA texture, containing classification information for every pattern, can be obtained. In Fig. 2.b) it is shown the output for *shader pass* 30.

A texture W^T is used for storing F_2 field neuron weights on the GPU. Each row stores a LTM trace w_j^i , just as in the training implementation. Input vector components stored in RGBA input textures are compared with corresponding column of weights on W^T . In each *shader pass*, the activation of the k th output neuron and the match function are computed for every input

Figure 2. Testing process of a fuzzy ART ANN on a GPU

pattern. These values are rendered into an RGBA output texture, which is used as input for the next iteration, again using the *ping-pong* technique. If the activation in pass k is bigger than the computed activation in pass $k - 1$ and the match criteria is satisfied, then the index category is updated on the output texture. Rendering both the index of the selected category and the match function to the output texture allows the expert to visually analyze the result: different levels on channel R represent different categories and *alpha* channel shows the level of resemblance of the input pattern to the selected category.

EXPERIMENTAL RESULTS

In order to measure the performance of the implementation, several tests were done on a CPU with a Fuzzy ART C++ self-written implementation and on a GPU using the previously described C++/OpenGL/Cg implementation. Timings were taken on a 3.2 GHz Pentium 4 with 1 GB RAM and a GeForce 7800GT 256 MB.

Performance of Fuzzy ART relays on several factors: length of the input pattern \tilde{I} , number of input patterns P presented to the network and number of committed categories N . During the learning process, N varies depending both on the grade of similarity between patterns and the *vigilance parameter* ρ (2). For the training tests, a synthetic *benchmark*, comprised of

several sets of patterns, was generated. In each set, the length of input vectors M and the number of expected categories N vary (see Table 1). In order to guarantee N was not too influenced by M and P , a *Multivariate Normal Distribution* was used for pattern generation. Being N the number of categories in a set of P patterns $\tilde{I}_p = (\vec{a}, \vec{a}^c)$, $p = 1 \dots P$, the k patterns belonging to category N_i within the set, were generated using a normal distribution for each vector $\vec{a} \sim N_N(\mu, \Sigma)$, and then obtaining its complement coding \vec{a}^c . In vector μ , the mean for every component is selected to be in the (0,1) range and covariances were set to null in covariance matrix Σ . Finally, parameters in the network were chosen to be $\rho = 0.9$, $\alpha = 0.05$ and $\beta = 1$.

Table 1 reveals that the training process takes more time to execute on the GPU than on the CPU. As stated before, learning is a sequential process, thus we cannot re-write Fuzzy ART learning algorithm for an optimal parallel execution. However, the proposed design demonstrated to be faster than a Matlab implementation of Fuzzy ART, where even a collection of 50×10^3 patterns with dimension 4 takes 380 s to train. Performance of training is expected to grow in applications where the number of committed nodes is very large, so that fragment processors are in use for longer periods of time.

For measuring the time taken by the testing process, a different collection of benchmarks was generated and the ANN was tested using previously stored LTM traces.

Table 1. Times for training and testing on a CPU and on a GPU

| M | P (x 10^3) | N | TRAIN | | TEST | | |
|------|-----------------|-----|---------|---------|---------|---------|---------|
| | | | CPU (s) | GPU (s) | CPU (s) | GPU (s) | SPEEDUP |
| 4 | 10 | 15 | 0,0582 | 4,2128 | 0,0535 | 0,0014 | 38,5 |
| | 50 | 59 | 0,4606 | 25,2468 | 0,4704 | 0,0145 | 32,4 |
| | 100 | 119 | 1,4212 | 53,8550 | 1,4954 | 0,0563 | 26,6 |
| 8 | 10 | 8 | 0,0595 | 4,7471 | 0,0545 | 0,0012 | 46,2 |
| | 50 | 50 | 0,5706 | 30,8801 | 0,5919 | 0,0157 | 37,8 |
| | 100 | 100 | 1,8734 | 65,3028 | 1,9809 | 0,0605 | 32,7 |
| 16 | 10 | 10 | 0,0743 | 6,0570 | 0,0702 | 0,0018 | 38,9 |
| | 50 | 55 | 0,9131 | 35,1509 | 0,9075 | 0,0300 | 30,3 |
| | 100 | 111 | 3,3745 | 70,2651 | 3,3425 | 0,1181 | 28,3 |
| 32 | 10 | 10 | 0,0961 | 6,2251 | 0,0932 | 0,0029 | 32,7 |
| | 50 | 50 | 1,4913 | 35,3596 | 1,4449 | 0,0523 | 27,6 |
| | 100 | 100 | 5,3758 | 74,8078 | 5,3725 | 0,2135 | 25,2 |
| MEAN | | | | | | | 33,1 |

In this case, the GPU demonstrated to be many times more efficient than the CPU (see Table 1). In the GPU-based testing implementation several input patterns can be categorized in parallel, deeply exploiting the GPU streaming programming model. As it is shown in Table 1, testing process can perform the classification of 32-component patterns between 100 different categories at a rate of 4.68×10^5 patterns per second and classify 4-component patterns between 15 different categories at a rate of 7.14×10^6 patterns per second.

FUTURE TRENDS

Described implementation of Fuzzy ART training algorithm on the GPU is still slower than a high-level programmed implementation on the CPU. In the proposed implementation patterns, which are to be learned by the network, are downloaded from the CPU to the GPU one by one causing GPU to stall, waiting for new data. This represents a serious bottleneck. Furthermore, when the number of committed categories is not very high, *arithmetic intensity* of the design is very low, because there are a limited number of operations that can be made with uploaded data. Future research tasks can include the use of *Pixel Buffer Objects* (PBOs), an OpenGL extension, to achieve fast asynchronous transfer rates from CPU to GPU memory.

CONCLUSION

AGPU implementation of a Fuzzy ART Neural Network following a *stream processing model* was introduced in this paper. This design successfully faces the problem of integrating both training and testing processes on a commodity graphics card following a *stream processing model*.

Fuzzy ART testing process is performed on the GPU up to x46 times faster than in a CPU allowing its use for real-time applications which involve pattern recognition and decision making. Training process, though, is still slower on the GPU than on the CPU.

GPUs are quickly evolving and every 6-9 months a new generation of improved processors is made publicly available. Forward compatibility of the presented implementation for future hardware releases is guaranteed and greater performance can be expected with newer cards.

KEY TERMS

ART (Adaptive Resonance Theory): Learning theory developed by S. Grossberg that is used in competitive neural systems and includes short-term-memory (STM) and long-term-memory (LTM) processes.

Fuzzy ART: Evolution of the ART1 neural network capable of learning normalized analog input patterns in an unsupervised way through the use of fuzzy operators.

Fuzzy Logic: Mathematical method originated from the fuzzy set theory, which allows the partial membership of elements in a set, dealing with approximate reasoning instead of exactly deduced from classical logic.

GPGPU (General-Purpose computation on GPUs): A recent trend in computer science consisting in the use of the *Graphics Processing Unit* (GPU), for doing expensive computational tasks rather than just computer graphics.

GPU (Graphics Processing Unit): A dedicated graphics rendering device very efficient at manipulating and displaying computer graphics, thanks to its highly parallel structure.

Neural Classifier: An artificial neural network utilized to identify input patterns as members of a pre-defined class (supervised classification) or as members of an unknown class (unsupervised classification).

Stream Processing: A paradigm for the execution of parallel processing operations exploiting *data-level parallelism* rather than *task-level parallelism* that provides incredible performance with minimal programming effort.

INTRODUCTION

This article presents a real-time Fuzzy ART neural classifier for skin segmentation implemented on a *Graphics Processing Unit* (GPU). GPUs have evolved into powerful programmable processors, becoming increasingly used in time-dependent research fields such as dynamics simulation, database management, computer vision or image processing. GPUs are designed following a *Stream Processing Model* and each new generation of commodity graphics cards incorporates rather more powerful and flexible GPUs (Owens, 2005).

In the last years *General Purpose GPU* (GPGPU) computing has established as a well-accepted application acceleration technique. The GPGPU phenomenon belongs to larger research areas: *homogeneous and heterogenous multi-core computing*. Research in these fields is driven by factors as the *Moore's Gap*. Today's uni-processors follow a 90/100 rule, where 90 percent of the processor is passive and 10 percent is doing active work. By contrast, multi-core processors try to follow the same general rule but with 10 percent passive and 90 percent active processors when working at full throughput. Single processor *Central Processing Units* (CPUs) were designed for executing general purpose programs comprised of sequential instructions operating on single data. Designers tried to optimize complex control requirements with minimum latency, thus many transistors in the chip are devoted to branch prediction, out of order execution and caching.

In the article *Stream Processing of a Neural Classifier I* several terms and concepts related to GPGPU were introduced. A detailed description of the Fuzzy ART ANN implementation on a commodity graphics card, exploiting the GPU's parallelism and vector capabilities, was given. In this article, the aforementioned Fuzzy ART GPU-designed implementation is configured for robust real-time skin recognition. Both learning and testing processes are done on the GPU using chrominance components in TSL (*Tint, Saturation and Luminance*) color space. The Fuzzy ART ANN implementation recognizes skin tone pixels at a rate of 270 fps on an NVIDIA GF7800GTX GPU.

BACKGROUND

Human body parts detection has important applications as a first step in many high-level computer vision tasks such as personal identification, video indexing systems and *Human-Machine Interfaces* (HMI). HMI needs real-time video processing while consuming as few system resources as possible. Skin color is widely used as a cue for detecting and tracking targets containing skin, such as faces and hands in an image. The final objective of skin color detection is to build a decision rule to segment skin and non-skin pixels in an image efficiently. The simplest solution defines skin colors as those that have a certain range of values in the coordinates of a color space. OpenVidia was one of the first computer-vision oriented developments able to run skin

tone segmentation on the GPU (Fung, 2005). For this purpose OpenVidia uses RGB (*Red, Green and Blue*) to HSV (*Hue, Saturation and Value*) color conversion and threshold filtering.

Statistical approaches for skin segmentation are based on the assumption that skin colors follow a certain distribution which can be estimated. These approaches normally make use of the chrominance components in a color space, thresholds and tunable parameters.

Neural Network approaches have been proposed to learn skin color distribution. Karlekar et al. used a MLP neural network to classify pixels into skin and non-skin colors (Karlekar & Desai, 1999). More complex models have been proposed to deal with changing conditions, such as varying illumination in the images. Sahbi et al. used an ANN for coarse level skin detection, and then the areas found were subjected to Gaussian color modeling with a fuzzy clustering approach (Sahbi & Boujemaa, 2000). Martínez-Zarzuela et al. used a GPU-based Fuzzy ART ANN implementation to learn skin colors in TSL (*Tint, Saturation and Luminance*) color space (Martínez-Zarzuela, Díaz, González, Díez & Antón, 2007). In their system, Fuzzy ART categorization process takes advantage of every fragment processor available in the GPU, so that several pixels can be tested simultaneously by the network, allowing recognition at high frame rates.

Some other researchers have made efforts for integrating different kinds of ANNs on the GPU for speeding up specific applications. Oh et al. developed a GPU-based MLP for text area classification in an image; achieving almost 20 times speed up over a CPU (Oh & Jung, 2004). Luo et al. implemented a MLP on the GPU for real-time ball recognizing and tracking in a soccer robot contest (Luo, Liu & Wu, 2005). Steinkraus et al. proposed using graphics cards for OCR and on-line handwritten recognition (Steinkraus, Simard & Buck, 2005). Finally, Bernhard et al. developed two image segmentation algorithms using spiking neural networks on the GPU (Bernhard & Keriven, 2006).

STREAM PROCESSING FOR ANN-BASED SKIN RECOGNITION

TSL Color Space

Color filtering is a powerful tool in computer vision applications including the detection and tracking of human

body parts. Color processing has low computational cost and is robust against geometrical transformations (e.g. rotation, scaling, transfer and shape changes). However, factors such as non-idealities in color cameras and illumination conditions can spoil the performance of filtering-based applications.

Color can be decomposed into three different components, one luminance and two chrominance components. Several researches have proved that skin colors have a certain invariance regarding chrominance components. Skin tone and lighting mainly affect the luminance value (Hsieh, Fan & Lin, 2005).

Different color spaces separating chrominance and luminance components have been used for skin color segmentation: YIQ, YCbCr, CIE-Lab, CIE-Luv, HSV, IHS and TSL (Phung, Bouzerdoun & Chai, 2005). In TSL color space (Terrillon, David & Akamatsu, 1998), a color is specified in terms of *Tint* (T), *Saturation* (S) and *Luminance* (L) values. TSL has been selected as the best color space to extract skin color from complex backgrounds (Duan-sheng & Zheng-kai, 2003) because it has the advantage of extracting a given color robustly while minimizing illumination influence. The equations to obtain the T, S and L components in normalized TSL space are:

$$T = \frac{1}{2\pi} \arctan\left(\frac{r'}{g'}\right) + \frac{1}{2}, \quad (1)$$

$$S = \sqrt{\frac{9}{5}(r'^2 + g'^2)}, \quad (2)$$

$$L = 0.299R - 0.587G + 0.114B, \quad (3)$$

where $r' = (r - 1/3)$ and $g' = (g - 1/3)$, being r and g the chrominance components of the normalized rgb color model. The values of T, S and L are normalized in the range [0,1]. For $R = G = B$ (achromatic colors), $T = 5/8$ and $S = 0$ are taken.

Fuzzy ART Off-Line Training on the GPU for Skin Recognition

Adaptive Resonance Theory (ART) systems are comprised of three layers or fields of nodes. Fuzzy ART is an extension of the original ART 1 system that incorporates computations from *fuzzy set theory* into the ART network, and thus making it possible to learn

and recognize both analog and binary input patterns (Carpenter, Grossberg & Rosen, 1991). The first field F_0 represents the input pattern; the upper field F_2 represents the active code or category of the input pattern being selected; the middle layer F_1 receives both bottom-up inputs from F_0 and top-down inputs from F_2 . The F_0 activity vector is denoted by $\vec{I} = (I_1, \dots, I_M)$ where each component I_i is within the $[0,1]$ interval. A useful rule for avoiding proliferation of categories is *complement coding*. If \vec{a} represents the on-response of the pattern, each component of the off-response \vec{a}^c is defined as $a_i^c \equiv 1 - a_i$. Then, the complement coded input comes $\vec{I} = (\vec{a}, \vec{a}^c) \equiv (a_1 \dots a_M, a_1^c \dots a_M^c)$ and $|\vec{I}| = M$ for every input pattern.

In order to train the ANN for skin recognition, complement coded TS features can be chosen, so that input patterns are defined as $\vec{I} = (\vec{a}, \vec{a}^c) \equiv (T, S, 1-T, 1-S)$. This way, in a GPU implementation, each feature vector can be stored using a single *texel* in an RGBA texture

Each node of the F_2 field has an associated weight vector or *Long-term Memory* (LTM) trace $w_j = (w_{j1}, \dots, w_{jM})$ which subsumes information both from bottom-up and top-down weight vectors. Initially, all weights are set to one, so each category is said to be *uncommitted*. When a category is first selected it becomes *committed* and the corresponding node in F_2 re-adapts its associated weights w_j . For each input \vec{I} and F_2 node j , the *choice function* T_j is defined by:

$$T_j(\vec{I}) = \frac{|\vec{I} \wedge w_j|}{\alpha + |w_j|}, \quad (4)$$

where the fuzzy MIN operator \wedge is defined by $(p_i \wedge q_i) \equiv \min(p_i, q_i)$ and the norm $|\cdot|$ is defined by $|\vec{p}| \equiv \sum_{i=1}^M |p_i|$. The system is said to make a *category choice* when at least one F_2 node becomes active when an input pattern is presented at the F_0 entrance.

The category choice is indexed by J , where $T_J = \max(T_j : j = 1 \dots N)$. Then, w_J is said to be a *fuzzy subset* of \vec{I} and it is fed down from F_2 in order to measure its resemblance to the input pattern \vec{I} . The system enters in *resonance* if the *match function* meets the *vigilance criterion*:

$$\frac{|\vec{I} \wedge w_J|}{|\vec{I}|} \geq \rho. \quad (5)$$

Fuzzy ART implementations on the CPU sequentially compute the activity for every node in field F_2 (4). Then, a sort operation is executed in order to know which neuron is most fired by the input pattern. If the category stored in this neuron resembles enough to the input pattern (5), its associated weights are updated with the new information; otherwise, next most fired neuron must be analyzed. Fuzzy ART implementations following a *stream programming model* can compute the activity of every output neuron simultaneously. Moreover, on a GPU it is possible to take advantage of processing units devised to operate on vector data, and thus to select the most fired neuron whose *match rate* is bigger than a *vigilance parameter* ρ at once. By using complement coding we drastically reduce proliferation of categories and force $|\vec{I}|$ to be constant ($|\vec{I}| = M = 2$) for every input pattern. This also allows for avoiding extra computing when calculating the *match rate* (5). In case vigilance criterion is met and training is switched on, vector w_j must be updated using:

$$w_j^{new} = \beta (\vec{I} \wedge w_j^{old}) + (1 - \beta) w_j^{old}. \quad (6)$$

In a GPU implementation of a Fuzzy ART ANN devised for skin recognition LTM traces have 4 components and can be stored in a one-dimensional RGBA texture W^T . This texture should be long enough to contain as many categories as could be committed during training process. However, only first N *texels* containing information from committed neurons must participate in the training process when computing T_j . This can be done on the GPU using *scissoring*, which allows rendering a quad of dimensions $1 \times N$ which does not cover the whole texture. Scissoring can be used also for updating just those *texels* that should change during training process (6).

Training patterns can be extracted from images containing skin regions. For the experimental results shown in this paper, skin regions were carefully selected from 3056-image Faces96 database (Spacek, 1996). Skin color distribution was estimated as a normal distribution through the *Minimum Covariance Determinants* (MCD) estimator (Rousseeuw & Driessen, 1999) and a total of 671438 input vectors were selected to train the ANN depending on their *mahalanobis* distance to the mean color of the modeled distribution. The ANN was trained fixing α parameter to 0.001 and varying the *vigilance parameter* in different training tests. Table 1

Table 1. Number of committed categories varying ρ

| ρ | 0.90 | 0.93 | 0.95 | 0.97 |
|--------|------|------|------|------|
| N | 9 | 15 | 33 | 71 |

Figure 1. Skin regions belonging to different committed categories varying ρ 

shows the number of committed categories depending on the value of ρ .

The larger the value of the vigilance parameter, the larger the number of committed skin categories by the network as level of resemblance between patterns belonging to different categories increases. Figures from 1b) to 1e) show different regions identified as skin categories by the network with ρ increasing from 0.90 to 0.97 respectively.

Fuzzy ART Real-Time Skin Recognition on the GPU

Once the ANN has been trained, computed LTM traces contain all the information that it is needed for skin recognition. Video sequences that have to be processed can be acquired using a conventional USB Webcam and every new frame can be uploaded to the GPU memory and stored in an RGBA texture. Then, a *shader* can be used to convert (R, G, B, A) color space pixels into $(T, S, I-T, I-S)$ feature vectors, which will be the input for the Fuzzy ART ANN.

During skin recognition, several input patterns can be categorized in a parallel fashion using every fragment processor available on the GPU. *Category choice* occurs through the execution of a *shader* for N times, being N the number of categories in field F_2 . In each pass, the *activation* of the j th output neuron (5) and the *match rate* (6) are computed for every input pattern and

rendered into an RGBA output texture, which will also contain the category index associated to each pattern. This RGBA texture and texture containing feature vectors are used as inputs for the next iteration, using the *ping-pong technique*. If the activation in pass j is bigger than the computed activation in pass $j-1$ and the *match criterion* is satisfied, then the *category index* is updated in the output texture. Finally, a post-processing stage can be used to generate an image where those pixels not belonging to any skin category are not rendered to the screen. Fig. 2 shows a global scheme of the system and the evolution of the skin recognition process through different *shader passes*.

Rendering both the index of the selected category and the *match rate* to the output texture is useful for analyzing results achieved. Different gray levels on channel R represent different skin categories committed during training process; on channel A, a value in the range $[0,1]$ represents the level of resemblance of every pixel in the original image to the selected skin category.

Figure 3 shows two images categorized by the ANN using different ρ values. As ρ increases, both hit rate and false alarm rate decrease. With $\rho = 0.90$ almost every skin pixel is correctly recognized, but several non-skin pixels (e.g. from the purple glasses) are included in some skin category by the network. These pixels are correctly not recognized as skin with $\rho = 0.97$.

Table 2 shows the performance of the system for different resolutions running on a dual-core 3.2 GHz Pentium 4 with 1GB RAM, GeForce 7800GTX 256 MB GPU (containing 24 fragment processors) and a generic webcam able to capture up to 90 fps at resolutions of 640x480 pixels. As the value of ρ and resolution increase, frame rate decreases. The number of frames that can be processed by the network strongly depends on the number of input vectors and the number of committed categories every pixel has to be tested to. Best performance is 270 fps, for a resolution of 320x240 pixels and $\rho = 0.90$.

FUTURE TRENDS

Described implementation of the GPU-based skin recognition system in this article was developed using a combined C++ / OpenGL (Shreiner, Woo, Neider & Davis, 2005) / Cg solution (Randima & Kilgard, 2003), and the algorithm had to be translated into graphics terms so that it could be mapped to the GPU (Harris, 2005). However, newer graphics cards from NVIDIA can be programmed using the CUDA (*Compute Unified Device Architecture*) software development kit. Before CUDA was available GPGPU required the use of a graphics API, which presents the wrong abstraction for general-purpose parallel computation, making GPGPU applications difficult to write, debug, and optimize. CUDA enables direct implementation of parallel computations in the C language using an

Figure 2. Global system architecture

Table 2. Frames per second for different resolutions and ρ values

| Resolution | 320x240 pixels | | | 352x288 pixels | | | 640x480 pixels | | |
|------------|----------------|------|------|----------------|------|------|----------------|------|------|
| ρ | 0.90 | 0.95 | 0.97 | 0.90 | 0.95 | 0.97 | 0.90 | 0.95 | 0.97 |
| fps | 270 | 89 | 42 | 212 | 68 | 32 | 71 | 23 | 11 |

API designed for general-purpose computation. It also includes standard FFT and BLAS libraries that will help researchers from different areas to exploit GPUs computational performance.

CONCLUSION

An implementation of a GPU-based Fuzzy ART Neural Network for real time skin recognition was introduced in this paper. This design successfully faces the problem of using a neural network for pattern classification when time is a major requirement. A robust and complete set of skin colors and a good selection of input features (chrominance components of TSL color space) are necessary to train the network so that it can recognize skin in real changing conditions.

Experimental results show system achieves excellent performance with an NVIDIA 7800GTX GPU video card, which includes 24 fragment *shaders* in the pipeline. Fuzzy ART skin recognition on the GPU can be the first stage in a complex computer vision application, like a human-machine interface or a video vigilance system.

KEY TERMS

ART (Adaptive Resonance Theory): Learning theory developed by S. Grossberg that is used in competitive neural systems and includes short-term-memory (STM) and long-term-memory (LTM) processes.

CUDA: A GPGPU technology that allows a programmer to use the C programming language to code algorithms for execution on the GPU. CUDA requires an NVIDIA GPU and special stream processing drivers.

Fuzzy ART: Evolution of the ART1 neural network capable of learning normalized analog input patterns in an unsupervised way through the use of fuzzy operators.

GPGPU (General-Purpose Computation on GPUs): A recent trend in computer science consisting in the use of the *Graphics Processing Unit* (GPU), for doing expensive computational tasks rather than just computer graphics.

GPU (Graphics Processing Unit): A dedicated graphics rendering device very efficient at manipulating and displaying computer graphics, thanks to its highly parallel structure.

Heterogeneous Multi-Core Computing: Design and analysis of algorithms and applications for heterogeneous multi-core processor architectures (e.g. IBM Cell processor).

Homogeneous Multi-Core Computing: Design and analysis of algorithms and applications for homogeneous multi-core processor architectures (e.g. GPUs).

Moore's Gap: Refers to the relatively modest incremental performance gains brought about by the increased number of transistors on current uni-processor dies despite increases in clock speeds.

Stream Processing: A paradigm for the execution of parallel processing operations exploiting *data-level parallelism* rather than *task-level parallelism* that provides incredible performance with minimal programming effort.

TSL Color Space: Color space based on *Intensity Hue Saturation* (IHS) color model. A color in this space is specified by *Tint* (T), *Saturation* (S) and *Luminance* (L) values.

A Study of the Performance Effect of Genetic Operators

Pi-Sheng Deng

California State University at Stanislaus, USA

INTRODUCTION

Performance of genetic algorithms (GAs) is mainly determined by several factors. Not only the genetic operators affect the performance of a GA with varying degrees, but also the parameter settings for genetic operators interact in a complicated manner with each other in influencing a GA's performance. Though many studies have been conducted for this cause, they failed to converge to consistent conclusions regarding the importance of different genetic operators and their parameter settings on the performance of GAs. Actually, optimizing the combinations of different strategies and parameters for different problem types is an *NP*-complete problem in itself, and is still an open research problem for GAs (Mitchell, 1996).

Recognizing the intrinsic difficulties in finding universally optimal parameter configurations for different classes of problems, we advocate the experience-based approach to discovering generalized guiding rules for different problem domains. To this end, it is necessary for us to gain a better understanding about how different genetic operators and their parameter combinations affect a GA's behavior. In this research, we systematically investigate, through a series of experiments, the effect of GA operators and the interaction among GA operators on the performance of the GA-based batch selection system as proposed in Deng (2007). This paper intends to serve as an initial inquiry into the research of useful design guidelines for configuring GA-based systems.

PARAMETER CONFIGURATION FOR GENETIC OPERATORS

It is commonly believed that crossover is the major operator of GAs, with mutation preventing the population from early convergence to a certain solution before an extensive exploration of other candidate solutions

is made (Holland, 1992a). Crossover enables GAs to focus on the most promising regions in a solution space; however, mutation alone does not advance the search for a solution. Crossover is also a more robust constructor of new candidate solutions than mutation (Spears, 1993).

However, Muhlenbein (1992) argues that the power of mutation has been underestimated in traditional GAs. According to Mitchell (1996), it is not a choice between crossover or mutation but rather the balance among crossover, mutation, and other factors, such as selection, that is all important. The correct balance also depends upon the details of the fitness function and the encoding. Furthermore, crossover and mutation vary in relative usefulness over the course of a run. Actually, the theoretical analysis of crossover is still to a large extent an open problem (Back, *et al.*, 1997).

In addition to the GA operators, the population size also affects the performance of GAs. The specification of the population size affects the diversification of the population body and the implicit parallelism of a GA, and will thus affect the quality of the generated solutions and the performance of the solution-generating process. Choosing an appropriate population size for a GA is a necessary but difficult task for GA users. Usually, the parameter settings for most GA applications are based on De Jong's recommendations (De Jong, 1975). According to De Jong's experiments with five problems in function minimization, the best population size was 50~100, the best crossover rate was about 0.6, and the best mutation rate was 0.001. In a later study, Spears & De Jong (1991) suggested a wider range for the crossover rate as 0.5~0.8. Mitchell (1996) also observed that it was common in GA applications to set crossover rate at 0.7~0.8.

However, Schaffer *et al.* (1991) asserted that the best settings for population size, crossover rate, and mutation rate were independent of the problems. In their study of a small set of numerical optimization problems, a very small population of size 20~30 with

a large crossover rate ranging from 0.75 to 0.95, and with a very small mutation rate ranging from 0.005 to 0.01 would produce the best performance. Grefenstette (1993) also reached similar conclusions in his study of parameter optimization for GAs, and suggested the following settings: population size 30, crossover rate 0.95, and mutation rate 0.01. While Schaffer *et al.* (1991) and Grefenstette (1993) advocated a very small population size, Goldberg (1989) and Liao & Sun (2001) argued for a much larger population size.

From the above discussion, the diverse recommendations on population size seem to indicate that population size interacts with some other factors not included in the previous research. In this paper, we investigated the effect of interaction among different parameters on a GA's performance. However, the choice of mutation rate needs to take into account, at least, the task complexity of an application. According to Mitchell (1996), it is impossible to specify an optimal setting for parameters in all different applications.

EXPERIMENTAL DESIGN

We focus mainly on investigating the effects of different combinations of parameter settings for genetic operators on our GA's performance, and compare our results with the claims made by previous research. We discuss the factors and parameter settings experimented in this study as below:

- **Task complexity:** Since the length of the solution string is usually a function of the complexity of the problem, we experiment with different parameter settings for two batch selection tasks of different complexity levels. One task has 30 products to be manufactured, 10 available tools, and 8 available machines. The other less complex task has 12 products, 6 available tools, and 4 available machines.
- **Representation scheme:** In this paper, we consider a common situation in FMSs in which if a product is selected in a batch for manufacturing, the entire quantity specified in the production table must be produced in the shift. Under this assumption, our batch selection task becomes a pseudo-Boolean optimization problem. This enables us to use a single binary bit to represent a component in a candidate solution. Therefore,

each candidate solution to the batch selection task can be encoded as a binary string of fixed length P , where P is the cardinality of the entire set of products under consideration.

- **Population size:** If the population size is too small, the GA will converge too quickly to find the optimal solution; however, if the population size is too large, the computation cost will be prohibitive. In this research, we investigate the effect of population sizes 10, 100, and 200, representing Small, Medium, and Large, on generating solutions for our batch selection problem.
- **Selection strategy:** We adopted the elitism strategy so that the best candidate solutions at each generation could be retained for the next generation. Though elitism is used to prevent the elite solution strings in a population from being altered by crossover or mutation, retaining too many elite individuals might cause the domination of the entire population by suboptimal, though highly fit, solution strings. This might lead to degeneration for the population eventually. The usual practice is to retain a small number of elite candidate solutions (Goldberg, 1989). In this research our system preserves two fittest candidate solutions on each iteration of forming new population.
- **Crossover parameter:** We adopt the standard crossover operator, i.e., the one-point crossover. The crossover rate is the probability that the crossover operator will be applied to a pair of candidate solutions selected for reproduction. In order to re-examine the different claims by previous research on the importance of different crossover rates, we experiment with three different crossover rates: 0.1, 0.5, and 0.9, representing three levels: High, Medium, and Low.
- **Mutation parameter:** The parameter *mutation rate* is used to control the rate of diversification via probabilistic conversion of each bit value in a candidate solution. However, a mutation rate approaching 1 will theoretically lead to a completely stochastic search with no succession from generation to generation. The usual practice is applying an occasional mutation to make a random change in the elements of a solution string. There are also various conclusions from previous research regarding the mutation rate. In this research we experiment with three different mutation rates: 0.001, 0.01, and 0.5, representing three levels: Low, Medium, and High.

- **Termination criteria:** A termination criterion can be a specified maximum number of generations, a target objective function value, a convergence threshold, or a lack of improvement in the best solution over a specified number of generations. In this research, our system will terminate when there is no improvement in the best solutions over 50 consecutive generations.

PERFORMANCE ANALYSIS FOR COMPUTATIONAL EXPERIMENT

The optimal-batch search process is conducted for each parameter combination until 50 feasible solutions are generated. We experimented with the combinations of three population sizes, three levels of the crossover rate, and three levels of the mutation rate for two tasks. Altogether, we conducted 4381 times of experimentation in generating 2700 feasible solutions. Performance analysis for each parameter setting is discussed for each of the two tasks under study.

Performance Analysis for the Task with Higher Complexity

The result of our experiment for the higher-complexity task is shown in Table 1. As suggested by Mitchell (1996), a GA's behavior had better be understood and described by macroscopic statistics, such as mean fitness in the population. Therefore, we compute the average performance and standard deviation in Table 1. The average performance of each parameter combination is obtained by averaging the best results over 50 feasible solutions.

From Table 1, we find out that for all different combinations of crossover rates and mutation rates, the average performance for *Pop Size* = 200 is always the best. This implies that there is no strong interaction among the three parameters. In addition, the standard deviation column indicates that when the population size is larger, the fluctuation of performance from different runs of generating optimal solutions tends to be smaller. Though populations of size 200 would yield the best performance in our experiment, the number of runs of simulation for generating 50 feasible solutions is also the largest. Populations of size 10 are most likely to generate feasible solutions which tend to have the lowest performance.

If we look across all different population sizes, it seems that when the crossover rate is set at a low value, e.g., 0.1, the mutation rate should be set at a very small value for the best result. When the crossover rate is set at a medium or high level, the mutation rate 0.01 favors the performance the most. Overall, there seems to have a tendency that across all levels of population size, *Mutation Rate* = 0.01 and a medium- or high-level crossover rate will generate the best result. This implies that there might have an interaction between the crossover rate and the mutation rate.

Across all different levels of the crossover rate, the combination of *Mutation Rate* = 0.01 and *Pop Size* = 200 tends to consistently yield the best result. This implies that there is a strong interaction between the population size and the mutation rate. Across all levels of the mutation rate, there is also a consistent pattern of effects on the system performance among different combinations of population sizes and crossover rates: the population size 200 combines with high crossover rates in generating the best result in Table 1. This seems

Table 1. Performance of different population sizes under different mutation rates and crossover rates

| Crossover Rate | Pop. Size | Mutation Rate = 0.001 | | | Mutation Rate = 0.01 | | | Mutation Rate = 0.5 | | |

(Note: # F/#T: the ratio of the number of feasible solutions generated to the total number of simulation runs.)

to indicate there is a strong interaction between the population size and the crossover rate.

Performance Analysis for the Task with Lower Complexity

The result of our experiment for the other task is shown in Table 2. From Table 2, *Mutation Rate* 0.5 tends to produce the best result with the smallest deviation. The same observations also hold for the *Pop Size* = 200. This indicates that there is no strong interaction among these three parameters. However, *Mutation Rate* = 0.5 and *Pop Size* = 200 also have the lowest number of feasible solutions. On the other hand, *Pop Size* 10 and *Mutation Rate* 0.001 are most likely to generate feasible solutions which tend to have the lowest performance. From Table 2, we cannot identify any consistent pattern of performance for the crossover rate. Similar to the previous case, the interaction between the crossover rate and the mutation rate does not have a consistent pattern of influence on the system performance across different population sizes. This implies the lack of strong interaction between the crossover rate and the mutation rate for the current case.

Overall, the combination of *Pop Size* = 200 and *Mutation Rate* = 0.5 seems to give the best result for all different levels of the crossover rate. This implies that there is a *significant* interaction between the population size and the mutation rate. However, we cannot identify a consistent pattern for the combination of the population size and the crossover rate or the mutation rate and the crossover rate. This implies that there is *lack* of an interaction within these two pairs of parameters.

FUTURE TRENDS AND CONCLUSION

Though Schaffer *et al.* (1991) and Grefenstette (1993) advocate a very small population size, our analyses for both tasks of high complexity and low complexity indicate that larger populations will generally favor the performance of our batch selection system more than smaller populations. Our result is consistent with Liao & Sun (2001). With the availability of a larger pool of diverse schemata in a larger population, our GA system will have a broader view of the “landscape” (Holland, 1992b) of the solution space, and is thus more likely to contain representative solutions from a large number of hyperplanes. This advantage gives a GA more chances of discovering better solutions in the solution space. However, Davis (1991) argues that the most effective population size is dependent upon the nature of the problem, the representation formalism, and the GA operators. We plan to analyze the GA performance for another application domain so that we can be more conclusive on the issue of the effective population size.

Though the solution performance of small populations is lower than that of large populations, the efficiency of small populations in generating feasible solutions, i.e., the ratio of number of feasible solutions to the total number of runs required to generate a certain number of feasible solutions, is indeed better than large populations, especially when the mutation rate is high. This can be evidenced by the #F/#T columns of Tables 1 and 2. In this sense, Schaffer *et al.* (1991) and Grefenstette (1993) are correct in their recommendation. This might be due to the fact that small populations have higher probability of developing the premature convergence problem.

Our analysis shows that our two tasks do not agree on the recommendation for the mutation rate. The task with higher complexity prefers a very small mutation rate, especially 0.01; while the less complicated task prefers a very large mutation rate, such as 0.5. In addition, high crossover rates will be better for complex tasks; while there is no conclusion for simple tasks. Contrary to the general belief regarding the major role of crossover, we did not find out crossover was as a determinant factor as population size or mutation rate in influencing the system performance. Part of our findings is similar to that of Pendharkar & Rodger (2004), who compared the performance of different types of crossover operators, including arithmetic, uniform, and one-point operators, for the design of GA-based artificial neural networks and found no significant difference among them. In addition, our findings on the role of mutation rate for tasks of different complexity complement Muhlenbein (1992) who contends that the power of mutation has been underestimated in traditional GAs.

Our analysis also shows mutation and crossover interact with the population size in different ways. The effect of mutation is strongly influenced by the population size in both tasks. For the task with higher complexity, the combination of a very large population size, such as 200, and a small mutation rate, such as 0.01, tends to generate a very good result. However, the less complex task needs a very large population and a very large mutation rate, such as 0.5, in order to yield the best results. On the other hand, the interaction between crossover and the population size is only found with the task of high complexity, and the interaction between mutation and crossover is barely found with the task of higher complexity only. More research work needs to be performed in order to understand better how the effects of crossover and mutation depend upon other details of a GA, such as the population size, the application domain, the fitness function, encoding, and selection.

S

KEY TERMS

Batch Selection: Selecting the optimal set of products to produce, with each product requiring a set of resources, under the system capacity constraints.

Fitness Function: The objective function of the GA for evaluating a population of solutions.

Genetic Operators: Selection, crossover, and mutation, for combining and refining solutions in a population.

Implicit Parallelism: A property of the GA which allows a schema to be matched by multiple candidate solutions simultaneously without even trying.

Landscape: A function plot showing the state as the “location” and the objective function value as the “elevation”.

NP-Complete Problems: The hardest problems in the class NP—the class of nondeterministic polynomial problems.

Schemata: A general pattern of bit strings that is made up of 1, 0, and #, used as a building block for solutions of the GA.

Supervised Learning of Fuzzy Logic Systems

M. Mohammadian

University of Canberra, Australia

INTRODUCTION

Conventionally modelling and simulation of complex nonlinear systems has been to construct a mathematical model and examine the system's evolution or its control. This kind of approach can fail for many of the very large non-linear and complex systems being currently studied. With the invention of new advanced high-speed computers and the application of artificial intelligence paradigms new techniques have become available. Particularly neural networks and fuzzy logic for nonlinear modelling and genetic algorithms [Goldberg, D. (1989)] and evolutionary algorithms for optimisation methods have created new opportunities to solve complex systems [Bai, Y., Zhuang H. and Wang, D. (2006)].

This paper considers issues in design of multi-layer and hierarchical fuzzy logic systems. It proposes a decomposition technique for complex systems into hierarchical and multi-layered fuzzy logic sub-systems. The learning of fuzzy rules and internal parameters in a supervised manner is performed using genetic algorithms. The decomposition of complex nonlinear systems into hierarchical and multi-layered fuzzy logic sub-systems reduces greatly the number of fuzzy rules to be defined and improves the learning speed for such systems. In this paper a method for combining sub-systems to create a hierarchical and multilayer fuzzy logic system is also described. Application areas considered are - the prediction of interest rate, unemployment rate predication and electricity usage prediction.

Genetic Algorithms can be used as a tool for design and generation of fuzzy rules for a fuzzy logic system. This automatic design and generation of fuzzy rules, via genetic algorithms, can be categorised into two learning techniques namely, supervised and unsupervised. In supervised learning there are two distinct phases to the operation. In the first phase each individual is assessed based on the input signal that is propagated through the system producing output respond. The ac-

tual respond produced is then compared with a desired response, generating error signals that are then used as the fitness for the individual in the population of genetic algorithms. Supervised learning has successfully applied to solve some difficult problems. In this paper design and development of a genetic algorithm based supervised learning for fuzzy models with application to several problems is considered. A hybrid integrated architecture incorporating fuzzy logic and genetic algorithm can generate fuzzy rules that can be used in a fuzzy logic system for modelling, control and prediction.

Fuzzy logic systems typically have a knowledge base consisting of a set of rules of the form

If (x_1 is A_1 and x_2 is A_2 and ... and x_n is A_n)
Then (z_1 is B_1 or z_2 is B_2 or ... or z_m is B_m)

where A_k , $k = 1, \dots, n$ are normalised fuzzy sets for n input variables x_k , $k = 1, \dots, n$, and where B_k , $k = 1, \dots, m$ are normalised fuzzy sets for m output variables z_k , $k = 1, \dots, m$. The heart of the fuzzy logic system is the inference engine that applies principles of intelligent human reasoning to interpret the rules to output an action from inputs. There are many types of inference engines in the literature, including the popular Mamdani inference engine, [Bai, Y., Zhuang H. and Wang, D. (2006)].

Given a fuzzy rule base with M rules and n antecedent variables, a fuzzy controller as given in Equation 1 uses a singleton fuzzifier, Mamdani product inference engine and centre average defuzzifier to determine output variables, has the general form for a single output variable, say z_1

$$z_1 = \frac{\sum_{l=1}^M y_k^l \left(\prod_{i=1}^n \mu_{A_i^l}(x_i) \right)}{\sum_{l=1}^M y_k^l \left(\prod_{i=1}^n \mu_{A_i^l}(x_i) \right)} \quad (1)$$

where y_k^l are centres of the output sets B_k^l and membership function μ defines for each fuzzy set A_i^l the value of x_i in the fuzzy set, namely, $\mu A_i^l(x_i)$. Common shapes of the membership function are typically, triangular, trapezoidal and Gaussian. A first step in the construction of a fuzzy logic system is to determine which variables are fundamentally important. It is known that the total number of rules in a system is an exponential function of the number of system variables [Raju G. V. S. and Zhou, J. (1993), Kingham, M., Mohammadian, M, and Stonier, R. J. (1998)]. In order to design a fuzzy system with the required accuracy, the number of rules increases exponentially with the number of input variables and their associated fuzzy sets to the fuzzy system. A way to avoid the explosion of fuzzy rule bases in fuzzy logic systems is to consider Hierarchical Fuzzy Logic systems [Raju G. V. S. and Zhou, J. (1993)]. Hierarchical fuzzy logic systems have the property that the number of rules needed to construct the fuzzy system increases only linearly with the number of variables in the system.

The idea of hierarchical fuzzy logic systems is to put the input variables into a collection of low-dimensional fuzzy logic systems, instead of creating a single high dimensional rule base for a fuzzy logic system. Each low-dimensional fuzzy logic system constitutes a level in the hierarchical fuzzy logic system. Assume that there are n input variables x_1, \dots, x_n then the hierarchical fuzzy logic system is constructed as follows [Raju G. V. S. and Zhou, J. (1993)]

- The first level fuzzy rule base for fuzzy system with n_1 input variables x_1, \dots, x_{n_1} which is constructed from the rules

If x_1 is A_1^l and ... and x_{n_1} is $A_{n_1}^l$, Then y_1 is B_1^l

where $2 \leq n_1 \leq n$, and $l = 1, 2, \dots, M_1$.

- The i 'th level ($i > 1$) fuzzy rule base for a fuzzy system with $n_i + 1$ ($n_i \geq 1$) input variables, which is constructed from the rules

If $x_{N_{i+1}}$ is $A_{N_{i+1}}^l$ and ... and $A_{N_i}^l$ and y_{i-1} is Then y_i is B_i^l

where

$$N_i = \sum_{j=1}^{i-1} N_j,$$

and $l = 1, 2, \dots, M_i$

- The construction of fuzzy rule bases for fuzzy systems continues until $i=l$ such that

$$N_i = \sum_{j=1}^{i-1} N_j = n,$$

that is, until all the input variables are used in one of the levels.

The first level has n_1 input variables x_1, \dots, x_{n_1} with one output variable y_1 , which is then sent to the second level as input. In the second level another n_2 variables $x_{n_1+1}, \dots, x_{n_1+n_2}$ and the variable y_1 are combined to produce the output variable y_2 , which is then sent to the third level. This procedure continues until all the variables x_1, \dots, x_n are used [Raju G. V. S. and Zhou, J. (1993), Kingham, M., Mohammadian, M, and Stonier, R. J. (1998), Magdalena, L. (1998), Cordon, O., Herrera, F., Hoffmann, F. and Magdalena, L. (2001)]. The number of rules in a hierarchical fuzzy logic system is a linear function of the number of input variable and their associate fuzzy sets [Kingham, M., Mohammadian, M, and Stonier, R. J. (1998)]. Other ways to reduce the fuzzy rules of a fuzzy logic system are

1. Fusing variables before input into the inference engine, thereby reducing the number of rules in the knowledge base,
2. Grouping the rules into prioritised levels to design hierarchical or multi-layered structures,
3. Reducing the size of the inference engine directly using notions of passive decomposition of fuzzy relations,
4. Decomposing the system into a finite number of reduced-order subsystems, eliminating the need for a large-sized inference engine.
5. Reducing the number of fuzzy sets of each input variable, thereby reducing the number of rules in the knowledge base of fuzzy logic system.

Using hierarchical fuzzy logic systems the typically the most influential parameters are chosen as the system variables in the first level, the next most important parameters are chosen as the system variables in the second level, and so on, [Raju G. V. S. and Zhou, J. (1993)]. In this hierarchy, the first level gives an approximate output which is then modified by the second level rule set, this procedure can be repeated

in succeeding levels of hierarchy. The number of rules in a complete rule set is so reduced to a linear function of the number of variables, but this number may still be high. Further, given that different hierarchical and multi-layered structures can exist, how can the fuzzy knowledge base and associated parameters in each layer be effectively learnt? A learning approach based on genetic algorithms is discussed in this paper for the determination of these knowledge bases and associated parameters.

VARIABLE SELECTION, RULE BASE LEARNING AND DECOMPOSITION

Interest Rate Prediction

In [Kingham, M., Mohammadian, M, and Stonier, R. J. (1998)], the authors used hierarchical fuzzy logic structures and multi-layered neural network structures for modelling and prediction of the Australian interest rate with 14 input variables, on actual data of key economic indicators that was a limited data set. Using expert knowledge from an economist the following input variables were chosen and placed into 5 different groupings, namely,

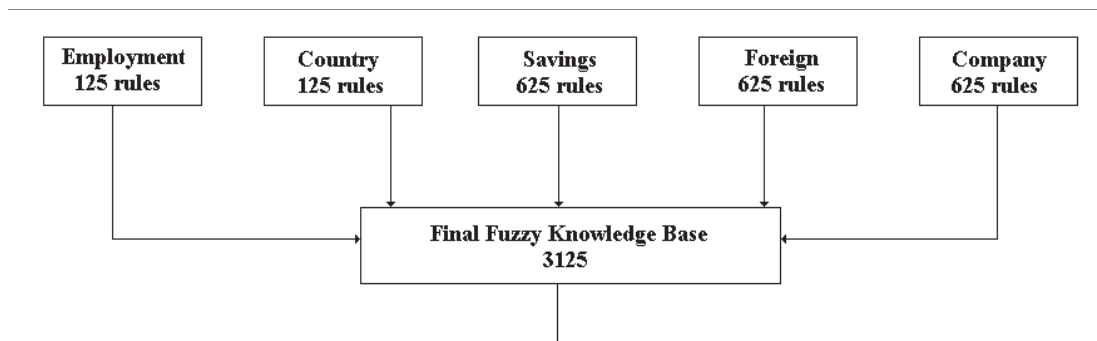

1. Employment (Job Vacancies, Unemployment Rate)
2. Country (Gross Domestic Product, Consumer Price Index)
3. Savings (Household Saving Ratio, Home Loans, Average Weekly Earnings)

4. Foreign (Current Account, RBA Index, Trade Weighted Index)
5. Company (All Industrial Index, Company Profit, New Motor Vehicles)

which then were formed into a two layered fuzzy system, see Figure 1.

The current interest rate was input into each of the five fuzzy systems in the first layer and the final output of the second layer was the predicted interest rate. It is assumed that the first layer gives a first iteration of the new interest rate and they are input into the second layer. But the output variables from the first layer do not necessarily have to be identified with the interest rate. Assuming there are five membership sets for all variables, including those entering the second layer, there are 5250 fuzzy rules in this structure. If all fourteen variables were input into a single layer fuzzy logic system structure there would be some 6 million rules (5^{14}). Hence there is a considerable reduction in the number of rules for this simple two layered hierarchical fuzzy logic system structure. But it is clear that this is not the only decomposition that could have been formed in grouping the variables, or in number of levels of the multi-layered structure. A genetic algorithm was used to learn the rules in this fuzzy system, and it was found that the hierarchical fuzzy logic system structure was accurate [Kingham, M., Mohammadian, M, and Stonier, R. J. (1998)]. Further research on this problem discussing different hierarchical fuzzy structures of three, four and five layers, and the learning of the fuzzy rule bases, was considered and can be found in [Mohammadian, M. and Kingham, M. (2004)].

Figure 1. Interest rate prediction

However there is still a question, Does a two layer hierarchical fuzzy logic system structure provides the best solution? To answer this question, one can start building three, four layer hierarchical fuzzy logic system structure by trial and error to possibly find the correct number of layers required. This could be cumbersome problem [Mohammadian, M. and Kingham, M. (2004)]. Genetic algorithms can be used to solve this problem by determining the number of layer in the hierarchical fuzzy logic system and the correct combination of fuzzy knowledge bases for each layer.

A genetic algorithm is developed in such a way to provide the possible best architecture for designing hierarchical fuzzy logic systems for prediction of interest rate in Australia [Mohammadian, M. (2002)]. Using the economic indicators five fuzzy logic systems were developed as described above. Genetic algorithms were

then used to design and develop a hierarchical fuzzy logic system. The hierarchical fuzzy logic system developed was then used to predict interest rate. For each of these group (as described earlier), the current quarter's interest rate is included in the indicators used.

For encoding and decoding of the hierarchical fuzzy logic system, first a number is allocated to each fuzzy logic system developed from group of indicators. For this simulation the number allocated to each group is shown below

1 = Employment, 2 = Country, 3 = Savings, 4 = Foreign, 5 = Company

The number of layers and the fuzzy logic system/s for each layer is determined by genetic algorithms. Genetic algorithms randomly encode each fuzzy logic

Figure 2. A three-layer hierarchical fuzzy logic system – 3125 fuzzy rules

Figure 3.

system into a number ranging from 1 to 5 for all possible combinations of the fuzzy logic systems. The level in the hierarchy in which a fuzzy logic system is allocated to, is also encoded in each string representing an individual in a population of genetic algorithms. A string is encoded this way can be represented as Figure 3.

Each individual string is then decoded into a hierarchical fuzzy logic system that defines the fuzzy logic system/s for each level of the hierarchical fuzzy logic system. The above string once decoded will provide a hierarchical fuzzy logic system as shown in Figure 2 above. The set of hierarchical fuzzy logic systems thus developed, are evaluated and a fitness value is given to each string. We define a satisfactory hierarchical fuzzy logic system as one whose fitness value (predicated interest rate) differs from the desired output of the system (in this case the actual interest rate) by a very small value. A calculated the average error of the system was used for the training set and tests sets using the following formula [Mohammadian, M. and Stonier, R. J. (1998)]

$$E = \frac{\sum_{i=1}^n abs(Pi - Ai)}{n}$$

where E is the average error, Pi is the Predicted interest rate at time period i , Ai is the actual interest rate for the quarter and n is the number of quarters predicted. By using genetic algorithms to design and develop hierarchical fuzzy logic system good results were obtained. The hierarchical fuzzy logic systems developed using genetic algorithms predict the interest rate to different degree of accuracy. It is however interesting to see that genetic algorithms is capable of providing different hierarchical fuzzy logic system structures for predicting the interest rate. It should be noted that genetic algorithm is also capable of finding the number of layers in hierarchical fuzzy logic system.

Prediction of Unemployment Rate

In [Mohammadian, M., Nainar, I. and Kingham, M. (1997)] a fuzzy logic system was developed for the supervised learning in predicting quarterly Unemployment rate in Australia. The following economic indicators were used as input to the Fuzzy Logic system.

- *The Unemployment Rate is the percentage of the labour force actively looking for work in the country.*
- *Interest Rate which is the indicator we are aiming to predict. The Interest Rate used here is the Australian Commonwealth government 10-year treasury bonds.*
- *Job Vacancies is where a position is available for immediate filling or for which recruitment action has been taken.*
- *Household Saving Ratio is the ratio of household income saved to households disposable income.*

Each input was split into five fuzzy sets giving a total of 625 rules. These rules form the fuzzy knowledge base of the system. A supervised learning strategy using of genetic algorithms [Mohammadian, M., Nainar, I. and Kingham, M. (1997)] was used to find the fuzzy knowledge base for the system. Using simulations it was shown that the fuzzy logic system is able to predict with a great deal of success the quarterly unemployment rate. The results achieved proved that the supervised learning strategy used accurately predicted fluctuations in the unemployment rate, and any small errors in the prediction could be reduced by increasing the training data and allowing the learning algorithm to run longer.

Electricity Load Prediction

In [Mohammadian, M. and Jentzsch, R. (2005)] a hierarchical fuzzy logic system using genetic algorithms for the prediction and modelling of daily electricity load fluctuations. The system is further trained to model and predict electricity consumption for daily peak. There are a number of possible indicators that could be used to predict the electricity load. These indicators that were used in this hierarchical fuzzy logic system are

Electricity load (is the past electricity consumption (hourly)),

Predicted Minimum Temperature is the predicted minimum temperature,

Predicted Maximum Temperature is the predicted maximum temperature,

Actual Minimum Temperature is the actual predicted minimum temperature,

Actual Maximum Temperature is the actual predicted maximum temperature,
Season is one of the four seasons in the year,
Day of the week is one of the seven days of the week,
Holiday is one of several public holidays in the year,
Time of day is divided here in 48 parts each consisting of 30 minutes.

The current electricity load is included in the input indicators to the system as the predicted electricity load is highly dependent on the current rate as there is only likely to be a fluctuation in the electricity load from current electricity load. The related indicators (inputs) are grouped together because of the common connection and relation among them such as temperature, time of day etc. These groups are as follows

- Predicted Temperature Group - This group contains Electricity Load, Predicted Minimum Temperature, Predicted Maximum Temperature, Time of day.
- Actual Temperature Group -This group contains Electricity Load, Actual Minimum Temperature, Actual Maximum Temperature, Time of day.
- Season day Group -This group contains, Electricity Load, Season (a value from 1 to 4 representing each season), Day of the week (two values, one for weekdays and zero representing weekend), Public Holiday (two values, one representing a public holidays and zero representing a working day), Time of day.

Using a hierarchical fuzzy logic system structure, it is possible to overcome this problem. The three groups

created for the electricity load prediction each produce a predicted electricity load. These are then fed into the next layer of the hierarchy where the final predicted electricity load is found (see Figure 4).

The total number of rules for the hierarchical fuzzy logic system is 1455. From simulation results it was found that the hierarchical fuzzy logic system is capable of making accurate predictions of the electricity load [Mohammadian, M. and Jentzsch, R. (2005)].

FUTURE TRENDS

The grouping of input parameters of the systems considered above was performed using expert knowledge. It would be interesting to use genetic algorithms to find out the relationships between the input parameters of such systems and compare the results obtained in this way with the grouping of parameters suggested by expert.

CONCLUSION

In this paper issues in the construction of a fuzzy logic system to model a complex (nonlinear) system, namely the decomposition into hierarchical/multilayered fuzzy logic sub-systems and the learning of fuzzy rules and internal parameters is considered. Whilst the decomposition into hierarchical/multi-layered fuzzy logic sub-systems reduces greatly the number of fuzzy rules to be defined and to be learnt, other issues arise such as the decomposition is not unique and that it may give rise to variables with no physical significance. For a problem with a large number of input variables, for

Figure 4. Hierarchical fuzzy logic system for electricity load prediction

example, the problem of interest rate prediction, the non-uniqueness of the decomposition yields numerous different structures to examine in order to find one which in some sense, is the ‘best’ structure.

KEY TERMS

Fusing Variables: Fusing variables is a method for reducing the number of rules in a fuzzy rule base. The variables are fused (combined) together before input into the inference engine, thereby reducing the number of rules in the knowledge base.

Fuzzy Logic: Fuzzy sets and Fuzzy Logic were introduced in 1965 by Lotfi Zadeh as a new way to represent vagueness in applications. They are a generalisation of sets in conventional set theory. Fuzzy Logic (FL) aims at modelling imprecise models of reasoning, such as common sense reasoning for uncertain complex processes. A system for representing the meaning of lexically imprecise proposition in natural language structure through the proposition being represented as fuzzy constraints on a variable is provided. Fuzzy logic controllers have been applied to many nonlinear control systems successfully. Linguistic rather than crisp numerical rules are used to control the processes.

Fuzzy Rule Base (Fuzzy If-Then rules): Fuzzy If-Then or fuzzy conditional statements are expressions of the form “If **A** Then **B**”, where **A** and **B** are labels of fuzzy sets characterised by appropriate membership functions. Due to their concise form, fuzzy If-Then rules are often employed to capture the imprecise modes of reasoning that play an essential role in the human ability to make decision in an environment of uncertainty and imprecision. The set of If-Then rules relate to a fuzzy logic system that are stored together is called a Fuzzy Rule Base.

Genetic Algorithms: Genetic Algorithms (GAs) are algorithms that use operations found in natural genetics to guide their way through a search space and are increasingly being used in the field of optimisation. The robust nature and simple mechanics of genetic algorithms make them inviting tools for search, learning and optimization. Genetic algorithms are based on computational models of fundamental evolutionary processes such as selection, recombination and mutation.

Genetic Algorithms Components: In its simplest form, a genetic algorithm has the following components:

1. ***Fitness*** - A positive measure of utility, called fitness, is determined for individuals in a population. This fitness value is a quantitative measure of how well a given individual compares to others in the population.
2. ***Selection*** - Population individuals are assigned a number of copies in a mating pool that is used to construct a new population. The higher a population individual's fitness, the more copies in the mating pool it receives.
3. ***Recombination*** - Individuals from the mating pool are recombined to form new individuals, called children. A common recombination method is one-point crossover.
4. ***Mutation*** - Each individual is mutated with some small probability $\ll 1.0$. Mutation is a mechanism for maintaining diversity in the population.

Hierarchical Fuzzy Logic Systems: The idea of hierarchical fuzzy logic control systems is to put the input variables into a collection of low-dimensional fuzzy logic control systems, instead of creating a single high dimensional rule base for a fuzzy logic control system. Each low-dimensional fuzzy logic control system constitutes a level in the hierarchical fuzzy logic control system. Hierarchical fuzzy logic control is one approach to avoid rule explosion problem. It has the property that the number of rules needed to construct the fuzzy system increases only linearly with the number of variables in the system

Supervised Learning: A learning method in which there are two distinct phases to the operation. In the first phase each possible solution to a problem is assessed based on the input signal that is propagated through the system producing output respond. The actual respond produced is then compared with a desired response, generating error signals that are then used as a guide to solve the given problems using supervised learning algorithms.

Support Vector Machines

Cecilio Angulo

INTRODUCTION

Support Vector Machines -- SVMs -- are learning machines, originally designed for bi-classification problems, implementing the well-known **Structural Risk Minimization (SRM) inductive principle** to obtain good **generalization** on a limited number of learning patterns (Vapnik, 1998). The optimization criterion for these machines is maximizing the margin between two classes, i.e. the distance between two parallel hyperplanes that split the vectors of each one of the two classes, since larger is the margin separating classes, smaller is the **VC dimension** of the learning machine, which theoretically ensures a good generalization performance (Vapnik, 1998), as it has been demonstrated in a number of real applications (Cristianini, 2000). In its formulation is applicable the **kernel trick**, which improves the capacity of these algorithms, learning not being directly performed in the original space of data but in a new space called feature space; for this reason this algorithm is one of the most representative of the called **Kernel Machines (KMs)**.

Main theory was originally developed on the sixties and seventies by V. Vapnik and A. Chervonenkis (Vapnik et al., 1963, Vapnik et al., 1971, Vapnik, 1995, Vapnik, 1998), on the basis of a separable binary classification problem, however generalization in the use of these learning algorithms did not take place until the nineties (Boser et al., 1992). SVMs has been used thoroughly in any kind of learning problems, mainly in classification problems, although also in other problems like regression (Schölkopf et al., 2004) or clustering (Ben-Hur et al., 2001).

The fields of Optic Character Recognition (Cortes et al., 1995) and Text Categorization (Sebastiani, 2002) were the most important initial applications where SVMs were used. With the extended application of new kernels, novel applications have taken place in the field of Bioinformatics, concretely many works

are related with the classification of data in Genetic Expression (Microarray Gene Expression) (Brown et al., 1997) and detecting structures between proteins and their relationship with the chains of DNA (Jaakkola et al., 2000). Other applications include image identification, voice recognition, prediction in time series, etc. A more extensive list of applications can be found in (Guyon, 2006).

BACKGROUND

Regularization Networks (RNs), obtained from the penalization inductive principle, are algorithms based on a deep theoretical background, but their purely asymptotic approximation properties and the expansion of the solution function on a large number of vectors convert them in a no practical choice in its original definition. Looking for a more reduced expansion of the solution some researchers observe the good behaviour of the SVM, being able to consider a finite training set as hypothesis in its theoretical discourse as well as building the final solution by considering nested approximation spaces.

As well regularization inductive principles as structural risk minimization establish inserting 'a priori' information on the shape of the solution without considering any assumption about the unknown probability density function relating working spaces. The regularization principle considers a regularizer or regularization operator ensuring find a good solution in asymptotic form on nested function spaces when the number of elements in the training set tends to be infinite. Besides, the SRM principle also is based on nested spaces but the solution is found by ensuring an upper bound for the risk functional considering only a finite set of empirical data.

Both inference processes are obviously not equivalents, but their similarities have been projected on the

learning methods having their theoretical background on these principles, in such a form that a number of researchers approaching the learning problem from different perspectives are implied in establishing a common framework allowing to deal SVMs and RNs like particular cases of a more general learning methodology, let us call it Kernel Methods (Campbell, 2000), when it is emphasized the key rule played by the kernel function generating the feature space, or Large Margin Classifiers (Cristianini, 2000), when the measure to be optimized to ensure maximal generalization is emphasized.

Both, results obtained and theoretical framework from SRM seem offer better theoretical warranties than other previous approaches when looking for solutions with good generalization for problems based on a finite empirical set. Hence, the integration of machine learning methods on mixed models is a state of the art research field. Besides, the use of Bayesian inference in these mixed models is being avoided because the user must beforehand define a probability density function.

SUPPORT VECTOR MACHINE

Let us consider a bi-classification problem (another kind of problems are analyzed in the cited references). Thus, let $Z = \{z_i = (x_i, y_i), i = 1, 2, \dots, n\}$ be a training set with $x_i \in X \subset \mathbb{R}^d$ as the input space and $y_i \in \{\theta_1, \theta_2\}$ (the output

space) ($\theta_1 \neq \theta_2$). Let us initially suppose that classes are linearly separable (two sets are linearly separable in n -dimensional space if they can be separated by an $d-1$ dimensional hyperplane) then a hyperplane, denoted by $\pi : w x - b = 0$ (where b is called bias), is sought which separates the two classes, that is $w x_i - b > 0$ if $y_i = \theta_1$ and $w x_i - b < 0$ if $y_i = \theta_2$. Nevertheless, there are many hyperplanes with this condition (see **Figure 1**), so a new condition is imposed that is the distance between the optimal hyperplane and the nearest training pattern (margin) is maximal. Let us see detailed this condition: In the first place without loss of generality let us suppose that $\theta_1 = 1$ and $\theta_2 = -1$. Hence, let β and α be the minimum (class $+1$) and the maximum (class -1) absolute values of the unbiased hyperplane effectively attained for some patterns $z_1 \in Z_1$ and $z_2 \in Z_2$ i.e.

$$\alpha = \max_{z_i \in Z_2} w x_i \text{ and } \beta = \min_{z_i \in Z_1} w x_i,$$

where Z_1 and Z_2 are the patterns belonging to the classes labelled as $\{+1, -1\}$ respectively. It is considered that $\alpha \leq \beta$, otherwise vector $-w$ is chosen. Thus, given a vector w , the margin is defined as the distance between parallel hyperplanes $\pi_\alpha : w x - \alpha = 0$ and $\pi_\beta : w x - \beta = 0$, that is

$$\text{margin} = d(\pi_\alpha, \pi_\beta) = \frac{\beta - \alpha}{\|w\|}$$

Figure 1. Type A denotes the class $+1$ (θ_1) and Type B denotes the class -1 (θ_2).

(see **Figure 1**). The natural choice for the bias, ensuring positive and negative outputs for the patterns in the respective classes, is

$$b = \frac{\alpha + \beta}{2}$$

The maximization of the margin has the objective to force the generalization of the found learning machine (Vapnik, 1995, Schölkopf et al., 2002).

The extension to non-linear functions of decision is carried out introducing the input space $X \subset R^d$ in another space, usually with higher dimension F , called feature or characteristics space which is endowed with an inner product, through a non-linear injection, $\phi : X \rightarrow F$ (this procedure is called kernel trick), such that the optimal hyperplane

$$f(x, w) = \langle \phi(x), w \rangle_F - b$$

is sought in the feature space F . Nevertheless, with the objective of defining in a unique way the searched hyperplane (canonical form) next restrictions should be added:

$$y_i f(x_i) \geq 1 - \xi_i \quad i = 1, 2, \dots, n$$

on the training set Z , where the slack variables $\xi_i \geq 0$ are introduced to allow that some examples exist violating the constraint imposed by the margin (soft-margin) because it should be considered the possibility that the classes to be separated are overlapped or that patterns contain noise that is the set Z can be a non-separable linearly. Hence, the function $f(x, w)$ allows defining the decision function as

$$h(x) = \text{sign}(f(x, w))$$

that is, given a new input x the label assigned by the machine is θ_1 if $h(x) = 1$ and θ_2 otherwise.

Thus the optimal hyperplane accomplishes the following problem of constrained optimization:

$$\begin{aligned} \text{Min} \quad & \frac{1}{2} \|w\|^2 + C \sum_{i=1}^n \xi_i \\ \text{s.t.} \quad & y_i f(x_i) \geq 1 - \xi_i \quad i = 1, 2, \dots, n \\ & \xi_i \geq 0 \quad i = 1, 2, \dots, n \end{aligned}$$

The solution vector can be written as

$$w = \sum_{i=1}^{SV} \alpha_i y_i \phi(x_i) \quad (1)$$

where SV is the number of training vectors which verify that their corresponding Lagrange multiplier α_i is no null (these vectors are called support vectors) (see **Figure 1**). Many other different approaches for defining SVM exist (González et al., 2006), nevertheless this formulation is the most usual.

From the equation (1), the optimal hyperplane can be written as:

$$f(x) = \sum_{i=1}^{SV} \alpha_i y_i k(x_i, x) - b$$

where $k(x_i, x) = \langle \phi(x_i), \phi(x) \rangle_F$ is a **Kernel** (a bivariate function accomplishing the Mercer's theorem) and b is calculated by using the Karush-Kuhn-Tucker (KKT) conditions.

For multi-classification problems, a set of possible labels $Y = \{\theta_1, \dots, \theta_\ell\}$ with $\ell \geq 2$ is considered. There are two main SVM-based approaches to solve these problems. A first one is the "all the classes at once", which solves these problems by considering all the instances from all the classes in a unique optimization formulation, whereas the other one is the "decomposition-reconstruction" architecture approach (multi-classification in two phases), using binary SVMs.

In the first case, several formulations exist (Vapnik, 1998, Cramer, 2001, Aioli, 2005), however among all of the proposed approaches to the maximal margin problem, that presented in Shashua et al. (2002) is the only one considering to maximize the exact expression of the margin between instances with different label, so the multi-classification problem is interpreted like an ordinal regression problem where the objective function is the sum of the inverse of the margins between classes.

In the case of multi-classification in two phases, the most usual multi-classification SVM approaches are 1-v-1 (one-versus-one) SVM and 1-v-r (one-versus-rest) SVM. In both approaches, a first decomposition phase generates several learning machines in parallel and a reconstruction scheme allows obtaining the overall output by merging outputs from the decomposition phase.

In the first phase of 1-v-r SVM, each machine takes in consideration all the classes; ℓ binary classifiers are trained to generate hyperplanes f_k , ($k=1,2,\dots,\ell$) separating training vectors with label θ_k from the remaining vectors. In the reconstruction phase (second phase), a labels distribution generated by the trained machines in the parallel decomposition is considered through a merging scheme. All the information provided by the training vectors is considered, main drawback being that it is not well designed to separate specific classes.

In the first phase of 1-v-1 SVM, each machine takes in consideration only two classes. In this approach,

$$\frac{\ell(\ell-1)}{2}$$

binary classifiers are trained to generate hyperplanes f_{kh} , $k, h=1,2,\dots,\ell$, $k < h$ separating training vectors with label θ_k from training vectors in class θ_h . Remaining training vectors are not considered in the optimization problem. In the reconstruction phase, a labels distribution generated by the trained machines in the parallel decomposition is considered through a merging scheme. Main drawback is that only data from two classes are considered for each machine in the decomposition procedure so output variance is high and any information from the rest of classes is ignored.

The 1-v-1 scheme is usually preferred because it takes less training time (Kressel, 1999) although some researches consider the 1-v-r scheme since this scheme has some advantages (Rifkin et al., 2004). Nevertheless according to (HsuLin2002) it would be difficult to say which one gives better accuracy.

FUTURE TRENDS AND CONCLUSION

A recursive problem when considering SVM is to reduce the computational cost when the QP problem is being solved.

SVM for classification is the most studied approach; however other problems as regression are not enough developed to be competitive versus other standardized research areas, like artificial neural networks. So, a long way still remains to be walked in this area.

A particular open research problem in the case of multi-classification is the implementation of the tri-class scheme. In this approach, one class is label as +1, another class as -1 and the rest of the classes as 0 which is forced to be encapsulated into a δ -tube, $0 < \delta < 1$, along the separation hyperplanes. The tri-class SVM improves standard algorithms treating 2-class classification problems during the decomposing phase of a general multi-class scheme by focusing the learning on

Figure 2. The circles are the class +1, the rectangles are the class 0 and the triangles are the class -1.

two classes, but using all the available information on the patterns (see **Figure 2**), so this approach can be seen as a mixed between the 1-v-r and 1-v-1 SVM. A second theoretical advantage of the “third-class approach” is the robustness of the reconstruction procedure (Angulo et al., 2003), which could drive to empirically expect a higher performance of the new approach in terms of accuracy (Angulo et al., 2006). Research should even include the study of theoretical generalization bounds for this kind of machine.

KEY TERMS

Generalization: It is the process of formulating general concepts by abstracting common properties of instances. In the context-specific of the SVMs means that if a decision function $h(x)$ is obtained from $x_i \in X \subset R^d$, this function is considered valid for all $x \in R^d$. It is the basis of all valid deductive inference and a process of verification is necessary to determine whether a generalization holds true for any new given instance.

Kernel Machine or Kernel Methods: Kernel machine owe their name to the use of kernel functions that enable them to operate in the feature space without ever computing the coordinates of the data in that space, but rather by simply computing the inner products between the images of all pairs of data in the feature space. This operation is often computationally cheaper than the explicit computation of the coordinates. Kernel functions have been introduced for sequence data, text, images, as well as vectors (Schölkopf et al., 2002).

Kernel Trick: This procedure consists on substituting the inner product in the space of input variables by an appropriate function $k(x, x')$ that associates to each two inputs an real number real that is $k(x, x') \in R$, for any $x, x' \in X$. Thus, this is a method for converting a linear classifier algorithm into a non-linear one by using a non-linear function to map the original observations into a higher-dimensional space; this makes a linear classification in the new space equivalent to non-linear classification in the original space.

Mercer's Kernel: A function $k : X \times X \rightarrow R$ is a Mercer's kernel if it is a continuous, symmetric and positive semi-definite function (Cristianini, 2000).

Regularization: It is any method of preventing overfitting of data by a model and it is used for solving ill-conditioned parameter-estimation problems.

Structural Risk Minimization (SRM) Inductive Principle: The main idea of the principle is to minimize a test error by controlling two contradictory factors: a risk functional from empirical data and a capacity for the set of real-valued functions (Vapnik, 1998).

The VC Dimension (for Vapnik-Chervonenkis Dimension): It is a number which is defined as the cardinality of the largest set of points that an algorithm can shatter, that is it is a measure of the capacity of a statistical classification algorithm (Vapnik et al., 1971).

A Survey on Neural Networks in Automated Negotiations

Ioannis Papaioannou

National Technical University of Athens, Greece

Ioanna Roussaki

National Technical University of Athens, Greece

Miltiades Anagnostou

National Technical University of Athens, Greece

INTRODUCTION

Automated negotiation is a very challenging research field that is gaining momentum in the e-business domain. There are three main categories of automated negotiations, classified according to the participating agent cardinality and the nature of their interaction (Jennings, Faratin, Lomuscio, Parsons, Sierra, & Wooldridge, 2001): the bilateral, where each agent negotiates with a single opponent, the multi-lateral which involves many providers and clients in an auction-like framework and the argumentation/persuasion-based models where the involving parties use more sophisticated arguments to establish an agreement. In all these automated negotiation domains, several research efforts have focused on predicting the behaviour of negotiating agents. This work can be classified in two main categories. The first is based on techniques that require strong a-priori knowledge concerning the behaviour of the opponent agent in previous negotiation threads. The second uses mechanisms that perform well in single-instance negotiations, where no historical data about the past negotiating behaviour of the opponent agent is available. One quite popular tool that can support the latter case is Neural Networks (NNs) (Haykin, 1999).

NNs are often used in various real world applications where the estimation or modelling of a function or system is required. In the automated negotiations domain, their usage aims mainly to enhance the performance of negotiating agents in predicting their opponents' behaviour and thus, achieve better overall results on their behalf. This paper provides a survey of the most popular automated negotiation approaches that

are using NNs to estimate elements of the opponent's behaviour.

The rest of this paper is structured as follows. The second section elaborates on the state of the art bilateral negotiation frameworks that are based on NNs. The third section briefly presents the multilateral negotiation solutions that exploit NNs. Finally, in the last section a brief discussion on the survey is provided.

NEURAL NETWORKS IN BILATERAL NEGOTIATIONS

In (Zhang, Ye, Makedon, & Ford, 2004) a hybrid bilateral negotiation strategy mechanism is described that supplies negotiation agents with more flexibility and robustness in an automated negotiation system. The framework supports a dynamically assignment of an appropriate negotiation strategy to an agent according to the current environment, along with a mechanism to create new negotiation rules by learning from past negotiations. These learning capabilities are based on feedforward back-propagation neural networks and multidimensional inter-transaction association rules. However, the framework is not adequately described and defined and the neural networks are not specifically instantiated. Additionally, there are neither quantitative nor qualitative experimental results for real world cases. Finally, the format of the input to the generic network that is presented is ambiguously described.

In (Zeng, Meng, & Zeng, 2005), the authors employ a neural network to assist the negotiation over very specific issues from a real world example. The network is trained online by the past offers made by the op-

ponent, while both the buyer and the seller agent have the ability to employ the proposed network. However, the experimental data sets are very restrictive and do not address the diversity of those that can be arisen in real scenarios. Additionally, the authors do not present the actual size of the hidden layer, a parameter that is extremely crucial with regards to the appropriateness to use such a network in a real time negotiation procedure by an agent with limited resources.

Furthermore, in (Rau, Tsai, Chen, & Shiang, 2006), the authors studied the negotiation process between a shipper and a forwarded using a learning-based approach, which employed a feedforward back-propagation neural network with two input data models and the negotiation decision functions. Issues of the negotiation were the shipping price, delay penalty, due date, and shipping quantity. The proposed mechanism was applicable to both parties at the same time and the network architecture was chosen based on past similar attempts, following a very restrictive pattern for the number of the hidden layer's neurons. The conducted experiments showed an overall improvement of the results for both negotiating parties, while the framework was proven stable and with small deadlock probability. However, as its authors support, further experimentation is required especially with regards to a wider variety of strategies and possibly more suitable network architectures for the hidden layer.

In (Carbonneau, Kersten, & Vahidov, 2006), a neural network based model is presented for predicting the opponent's offers during the negotiation process. The framework was tested over a specific set of experimental data collected from other existent frameworks and it is highly adjusted to these data. The purpose of this solution is not only to predict the opponent's next offer, but also the perception for the specific procedure, i.e. an overall vision on why everything is happening and where the procedure is led. Thus, the prediction of the opponent's next round offer is only a part of the network's output. However, the chosen experiment set is constrained and doesn't examine the effectiveness of the framework on diverse strategies as those proposed in the very first steps of the area and are now mainly used (Faratin, Sierra, & Jennings, 1998). Additionally, although the authors support the view that their framework is proper for real-time environments, the fact is that the resulted network is difficult to be online trained, mainly because of its size and the resources that are required for such training. Thus, this network

architecture is probably inappropriate for mobile agents' environments, and something smaller and more specific should be designed, due to the limitations that these environments share.

Moreover, in (Oprea, 2003), the author presents a shopping agent, which is capable of negotiating in online bilateral, multi-issue procedures using an offline created and trained feedforward neural network in order to increase its profitability by adapting its behaviour according to its opponent's. The purpose of the neural network's application on each procedure is to predict the opponent's next offer on a round by round basis and thus, model its behaviour and intentions in order to finally achieve a better or even the best possible deal. With the exploitation of the neural network the shopping agent can decide during the online phase of negotiation, which is the opponent's strategy and estimate its reservation value. Concerning the experiments conducted, the author uses the well-justified negotiation tactics presented in (Faratin, Sierra, & Jennings, 1998) in order to test the proposed solution and concludes that the framework is working well in case of medium or long term agents' deadlines. However, the results presented are not thoroughly justified and more extreme opponent strategies should be tested in order to decide on the network's adequacy for such environments. Probably, the three hidden layer neurons might not be sufficient for such cases and long-term estimations.

Finally, Papaioannou et al. have recently designed and evaluated several single-issue bilateral negotiation approaches, where the Client agent is enhanced with Neural Networks. More specifically, in (Roussaki, Papaioannou, & Anagnostou, 2006), the Client agent uses a lightweight feedforward back-propagation NN coupled with a fair relative tit-for-tat imitative tactic, and attempts to estimate the Provider's price offer upon the expiration of the Client's deadline. This approach increases the number of agreements reached by one third in average. In (Papaioannou, Roussaki, & Anagnostou, 2006), the performance of MLP and RBF NNs towards the prediction of the Provider's offers at the last round has been compared. The experiments indicate that the number of agreements is increased by ~38% in average via both the MLP- and the RBF-assisted strategies. Nevertheless, the overall time and the number of neurons required by the MLP are considerably higher than these required by the RBF. In (Roussaki, Papaioannou, & Anagnostou, 2007), MLP and GR NNs have been used by the Client agent in order to identify the unsuccessful

ful negotiation threads (UNTs) at an early stage, thus terminating them long before the deadlines expire. It has been observed that the MLP NN detects more than 90% of UNTs in average, outperforming by little the GR NN. Finally, in (Papaioannou, Roussaki, & Anagnostou, 2007), the performance of MLP and RBF NNs has been compared with cubic splines, least-square-based polynomial approximators, exponential approximators and Gaussian approximators, in order to predict the future offers of the negotiating Provider Agent. The wide experimental evaluation conducted indicates that both the MLP- and the RBF-assisted negotiation strategies perform almost equally well and outperform the other four approximator-assisted strategies. In this paper, the proposed framework is extended to address multi-issue negotiations considering the significance of the issues under negotiation for the negotiating party, as well as their degree of interdependency. A disadvantage in the aforementioned NN-based negotiation frameworks is that they have only been evaluated in case the Provider agent adopts a time-dependent strategy.

NEURAL NETWORKS IN MULTILATERAL NEGOTIATIONS

In (Oprea, 2001), the use of a small-scaled feedforward neural network is attempted in order to predict the opponent agent's behaviour. In this framework the enhanced agent is negotiating against an opponent that is not equipped with any learning or other intelligent mechanism. The neural network is properly constructed and trained at every round to respond with the opponent's next value at each negotiation step using only the three prior offers issued by the opponent. This fact makes the step-by-step computation feasible in real time procedures, but not necessarily reliable. However, the proposed approach was proved adequate only in cases when either both agents (or at least the opponent agent) have long-term deadlines.

A different usage of the neural networks' potential is presented in (Shibata, & Ito, 1999), where the authors are mainly concerned with the communication between agents. In principal, they divide the agents' communication into two classes with respect to its meaning. The first one incorporates the cases where the agent transmits the observed information while the second those where the agent's intention is transmitted. The framework exploits an Elman recurrent neural network

with feedback loops, especially for the latter class of cases. The network assists the agents to avoid possible negotiation deadlocks, although nothing is known apriori with regards to their strategy or resources. The network keeps the past information and adapts online its corresponding agent's behaviour accordingly in order to avoid collisions. The proposed framework was also tested with four agents leading to promising results. However, the authors don't propose or apply techniques for higher profitability of the participating agents but only for collision avoidance by learning the opponent's intention. Additionally, a recurrent neural network is a complex structure and seems inappropriate for application in low resources agent environments.

Furthermore, in (Abreu, Canuto, & Santana, 2005) the authors present a comparative analysis of some negotiation methods used in a multi-neural agent system, called NeurAge. This system is composed of several neural classifiers, called neural agents, and its main aim is to overcome some drawbacks of multi-classifier systems and, as a consequence, to improve their performance. These neural agents provide a common output, which results after negotiation among them and it is the system's output. For this purpose, three different negotiation methods are evaluated: the game theoretic, the auction based and the confidence based ones. The results prove that the proposed approach is valuable for such classifier systems and might end up being valuable in cases where tactic classification should be conducted. However, the system is inappropriate for online procedures, requires cooperation between multiple neural agents and has not been tested on real negotiation tactics' numerical data. Therefore, the results might be valuable when a classification scheme is required, but are probably inappropriate as a future prediction pattern.

On the other hand, (Veit, & Czernohous, 2003) present the results of enhancing consumer agents with several machine-learning algorithms in a properly designed electronic market with one static supplier. The results prove that under very specific circumstances the neural network assisted agent performs worse than a simple Q-learning assisted agent that maintains a specific set of values for the learning procedure in an a-priori instantiated matrix. However, the scenarios are very restrictive and in no case address the characteristics of real world ones where the application of similar table based agents would fail mainly due to the diversity of the potential solution spaces for each

negotiation. Besides, the authors themselves admit this remark, including it in their future plans.

In (Park, & Yang, 2006), the authors propose a negotiation agents system based on the incremental learning of a feedforward neural network in order to increase the efficiency of bilateral negotiations and to improve the applicability towards multilateral negotiations. The network is triggered with values that are extracted after a utility evaluation procedure and at each round the output is forming the next counter-offer of the party. With regards to the generalization to the multilateral case, the proposed approach is based on matching all sellers and all buyers in pairs among all possible ones, following practical criteria as the common negotiation range term used, indicates. The experimental results show that the proposed system achieves up to 2% more agreements and carries out the negotiations at least twice as fast as others with similar settings.

In (Wang, Chai, & Huang, 2005), the authors attempt to solve the problem of selecting a selling agent that meets buyer user's requirements as well as his utility constraints as those represented by the corresponding intelligent agent. The problem is solved by choosing the seller before the negotiation and thus, the accuracy of the negotiation and the buyer's utility are improved. In order to fully utilize negotiation history, this paper transforms the problem of choosing seller into a K-armed bandit problem. The utility function is a joint summation of the utilities of both the buyers and the sellers, while the buyer uses a properly learned neural network in order to learn its opponents' preferences and finally choose the one that will lead to the best agreement. The advantage of this framework is that the buyer's neural network learns off-line and only uses the results for the online procedure. Thus, there is not substantial impact on the real procedure.

Finally, in (Liu, & You, 2003), a fuzzy neural network is proposed to deal with the uncertainties in real world shopping activities, such as consumer preferences, product specification, product selection, price negotiation, purchase, delivery, after-sales service and evaluation. The fuzzy neural network manages to achieve an automatic and autonomous product classification and selection scheme to support fuzzy decision-making by integrating fuzzy logic technology and the back-propagation feedforward neural network. In addition, a visual data model is introduced to overcome the limitations of the current web browsers that lack flexibility for customers to view products from different

perspectives. The experimental results demonstrate the feasibility of the proposed approach for web-based business transactions.

CONCLUSION AND DISCUSSION

In this paper, a brief survey of the most popular research efforts in the field of NN-assisted automated negotiations is presented. An important observation that can easily be made is that there is a substantial diversity on the purposes that the NNs are used for in this domain. For instance, in some cases they aim to estimate the opponent's future offers, whereas in other cases they assist the negotiating agent on selecting the best tactic that should be used in order to increase its potential utility. Even though the usage of NNs in automated negotiations may enhance various aspects of their performance and results, there are some cases where they are not suitable. For example, they perform far better when they are trained off-line, thus being less suitable when no a-priori knowledge is available. In general, it is preferable that relatively small NNs that are trained off-line are used, but if this is not possible, it is better to use NNs of minimal size that are trained on-line, risking however that they will eventually not be suitable enough. Furthermore, if the negotiation strategy of the opponent is not consistent, thus frequently demonstrating sharp changes in the type or configuration of the tactic used, the NNs often fail to adjust. In case the opponent employs imitative negotiation strategies, the usability of NNs in estimating the opponent's behaviour is questionable. Finally, if the agent has low storage and processing resources available, the NNs that can be employed need to be so lightweight that they considerably lack flexibility. Despite these shortcomings, it is expected that NNs will gain a considerable share in the learning-enabled negotiating agents in the electronic marketplace.

KEY TERMS

Automated Negotiation: It is the process by which group of actors communicate with one another aiming to reach to a mutually acceptable agreement on some matter, where at least one of the actors is an autonomous software agent.

Bilateral Negotiation: A negotiation procedure, where exactly two parties are involved, i.e. a client and a provider.

Multilateral Negotiation: A negotiation procedure, where more than two parties are involved, i.e. multiple clients and/or providers negotiate simultaneously.

Multi-Layer Perceptron (MLP): A fully connected feedforward NN with at least one hidden layer that is trained using back-propagation algorithmic techniques.

Neural Network (NN): A network modelled after the neurons in a biological nervous system with multiple synapses and layers. It is designed as an interconnected system of processing elements organized in a layered parallel architecture. These elements are called neurons and have a limited number of inputs and outputs. NNs can be trained to find nonlinear relationships in data, enabling specific input sets to lead to given target outputs.

Radial Basis Function (RBF): Function that involves a distance criterion with respect to a centre, such as a circle, ellipse or Gaussian.

RBF NN: It is an artificial NN, the activation functions of which are radial basis functions. It has two layers of processing, where the first maps the input onto each RBF neuron in the other (hidden) layer.

Swarm Intelligence Approach for Ad-Hoc Networks

INTRODUCTION

Wireless ad-hoc networks are infrastructureless and they consist of nodes that come together and start communicating dynamically without requiring any backbone support. The nodes can enter and leave the network at will and can move about in the network at will.

Ad-hoc networks present the perfect test-beds for bio-inspired computing algorithms. Both ad-hoc networks and bio-inspired computing approaches are characterized by self-organization, feedback and structural and functional complexity (Toh, 2002) (deCastro & Von Zuben, 2005). Hence, bio-inspired algorithms often provide us an opportunity to solve the most complex problems of ad-hoc networks in a satisfactory manner. In this chapter, we present the works done in the field of ad-hoc networks using bio-inspired Swarm Intelligence (SI). In particular, we look at how we can use Ant Colony Optimization (ACO) technique, a SI technique, for optimal routing in ad-hoc networks.

BACKGROUND

Most major bio-inspired algorithms have found implementations in the field of ad-hoc networks. Before delving into the details of the applications of ACO techniques for solving problems in ad-hoc networks, for contextual alignment, let us broadly review some of the applications of the different classes of bio-inspired algorithms to ad-hoc networks. Barolli, Koyama, & Shiratori (2003) presented a Genetic Algorithm to solve QoS routing for ad-hoc networks, while Di Caro, Ducatelle, & Gambardella (2004) used ACO technique to develop a nature inspired routing algorithm for ad-hoc

networks. On similar lines, Wedde & Farooq (2005) presented BeeAdHoc – a routing algorithm inspired from foraging behavior of honey-bees. Neural Networks too have been extensively used in ad-hoc networks for providing solution to the problems of routing (Vicente, Mujica, Sisalem, & Popescu-Zeletin, 2005), intrusion detection (Zhang & Lee, 2000) and clustering (Ai-bin, Zi-xing, & De-wen, 1993).

ACO is one of the most popular techniques among different bio-inspired techniques and has been extensively studied and deployed for solving problems as varied as Vehicular Routing Problem (VRP) (Toth & Vigo, 2001) to Single Machine Total Weighted Tardiness Problem (SMTWTP) (Abdul-Razaq, Potts & Van Wassenhove, 1990) to Graph Colouring Problem (Vesel & Zerovnik, 2000).

ACO was introduced by Marco Dorigo in his PhD. thesis as Ant System (AS). It was initially aimed at solving the popular Travelling Salesperson's problem. Though the solution provided by AS was suboptimal when compared with other specialized solutions, it underlined a method which models the foraging behaviour of ants to solve complex problems of computer science.

MAIN FOCUS OF THE CHAPTER

As mentioned earlier, the primary focus of this Chapter is to illustrate the applications of bio-inspired ACO techniques in the field of ad-hoc networks. We start by introducing the concepts of SI. Then, ACO concepts and their implementations in ad-hoc networks are discussed in detail. We first present and explain properties of ant colony that can enable to find the shortest path between

the source of the food of the ants and their colony using the concept of *pheromone*. We explain the concept of artificial ants and then present the *Random Proportional Transition Rule* (Dorigo & Stützle, 2003). We, then, describe in detail, the *AntHocNet* algorithm (Di Caro, Ducatelle, & Gambardella, 2004), which uses the ACO technique for routing data in ad-hoc networks.

SWARM INTELLIGENCE

Social insects such as ants, bees, wasps and termites and organisms such as fishes and birds rely on local communication to achieve distributed control. While insects such as ants, bees and termites rely on indirect communication through environment (also often referred to in the literature as *Stigmergy*), birds are dependent on direct but localised communication.

Nonetheless, all of these techniques aim at developing a system in which each element of the system works together to establish autonomy. The elements co-operate with each other locally to make the system much more adaptable and robust to changes and errors. Since these are the main aims of the design of ad-hoc networks, SI algorithms are effectively employed for

solving routing and Quality-of-Service (QoS) problems in ad-hoc networks.

ACO

Natural ants have a property that they always find the shortest path to the food source from their nests. This property can be illustrated by the experiments explained in (Goss, Aron, Deneubourg, & Pasteels, 1989) and (Deneubourg, S., S., & J., 1990). The set up of the experiments is illustrated in Figure 1 and Figure 2.

In Figure 1, the path between the nest and the food source are equal. It was found that roughly 50% of the ants were using each path. On the other hand in the set up shown in Figure 2, when the paths are unequal, it was found that after some time nearly all the ants were using the smaller path. This phenomenon can be explained using the following argument.

It was found that the ants mark the path that they take by a chemical named *pheromone*, thereby guiding other ants to take that path. Its implication is that the ants choose a path on the basis of the amount of pheromone lying on that path. In Figure 2, when the first group of ants start from their nest, they choose each path with equal probability. So, about half of the ants start moving on each path. The ants using the smaller

Figure 1. Same path lengths¹

Figure 2. Different path lengths²

path reach point B first. Since no pheromone is present, the group again divides into two with equal number of ants turning towards the nest and other half going back via the longer path. When the ants coming from the longer path (which remain unperturbed by the ants coming back from that path) reach point B, they face a choice between going towards the food source or going back towards point A using the smaller path. Since pheromone on path to the food source is smaller than that on the path going back to point A, more ants use this path, thereby increasing the pheromone quantity on shorter path even further. When the second group of ants start from the nest and reach point A, more ants chose the smaller path since the pheromone value on that path is higher thereby increasing the pheromone quantity even further. This can be considered as special type of *reinforced learning* mechanism. Also, the chemical *pheromone* evaporates easily, thus reducing the pheromone level on both the paths. Ultimately the pheromone level on the longer path drops to nearly zero and hence all the ants use the smaller paths after some time. Note that the path from point B to food source is negligibly small and hence the pheromone level on it too increases rapidly and this becomes the selected path at point B instead of the longer path going back.

As mentioned earlier, Marco Dorigo modelled this behaviour of ants mathematically on small agents called *Artificial Ants*. These ants take probabilistic decisions over a set of possible solutions as a function of pheromone value associated with that path and heuristic information which is based on the input data. During each iteration, a solution is chosen with a probability which is given by (deCastro & Von Zuben, 2005):

$$\frac{\tau_{ij}^{\alpha} \cdot \eta_{ij}^{\beta}}{\sum_{h \in S} \tau_{ij}^{\alpha} \cdot \eta_{ij}^{\beta}} \quad (1)$$

In Equation (1), τ_{ij} refers to the pheromone level and η_{ij} is the heuristic information.

Equation (1) is called the *Random Proportional Transition Rule* (deCastro & Von Zuben, 2005). The pheromone and heuristic information can be weighted using α and β and hence, $\alpha, \beta \in R^+$. The pheromone value of a solution can also be updated on the basis of its performance by a process of *reinforcement*. The pheromone levels for good solutions can be reinforced by updating pheromone values on such solutions. This leads to faster convergence on optimal solutions.

In addition to this, pheromones are evaporated proportionally on all solutions. If ρ denotes the evaporation rate, the pheromone value of a solution is found by multiplying it by a factor of $(1 - \rho)$. The purpose of evaporation is opposite to that of reinforcement. It aims at avoiding too rapid convergence of the solution, which might lead to a sub-optimal solution (Dorigo & Stützle, 2003). Evaporation implements convenient *forgetting*, leading to exploration of a bigger solution space.

AntHocNet

AntHocNet (Di Caro, Ducatelle, & Gambardella, 2004) is an Ant Colony-based routing technique for ad-hoc networks. It is a hybrid algorithm which relies on reactive route set up combined with proactive route probing, maintenance and improvement. It is an on-demand routing algorithm, which means that the paths between the source and destination are set up as and where required and is not computed beforehand. *AntHocNet* is also a table-based routing protocol which means that the tables are used by each node to keep track of all the paths from that node to other nodes in the network. Every on-demand routing algorithm in ad-hoc networks has the following three functionalities (Toh, 2002).

1. Route Discovery: To find a route between the source and the destination.
2. Route Selection: If multiple routes are present, an algorithm selects the route(s) that are used for the purpose of routing. This might include selecting routes from a given table of routes.
3. Route Maintenance: To take suitable actions when routes break due to movement of nodes or link failure.

Though an algorithm may offer functions related to security, fault tolerance and other application-specific functionalities, these are the three basic functionalities present in almost every routing algorithm. We would now discuss how *AntHocNet* implements all the three functionalities.

Route Discovery

As mentioned earlier, an *AntHocNet* is an on-demand routing protocol. Routes are found 'on-the-go'. In *AntHocNet*, small control packets called *ant agents*

are used for transferring control information within the network. When a source node s wants to communicate with a destination node d , it looks for a path in its *pheromone table*. If it does not find any path, it broadcasts a *reactive forward ant* F_d^s . Ant agents, which are copies of each other (like the ones that are broadcasted), are said to be belonging to the same *generation* of ants. A node i that receives the ant, in turn, looks for a path to the destination d in its own pheromone table. A pheromone table stores entries in the form T_{nd}^i , where T_{nd}^i represents the suitability of going over to neighbouring node n to reach d . If pheromone information is available, the next node is chosen on the basis of the *Random Transition Rule* given in Equation (1) (Di Caro, Ducatelle, & Gambardella, 2004). A node n is chosen with a probability P_{nd} (Di Caro, Ducatelle, & Gambardella, 2004).

$$P_{nd} = \frac{(T_{nd}^i)^{\beta_1}}{\sum_{j \in N_d^i} (T_{jd}^i)^{\beta_1}}, \quad \beta_1 \geq 1, \quad (2)$$

Here, N_d^i represents the set of neighbours over which path to the node d is known. On comparing Equation (1) with Equation (2), the reader would notice that the value of α denoting the importance of heuristic information is zero here and β_1 signifies the parameter which can be used to control the exploratory behaviour of ants.

If the node i does not have any entry in its pheromone table, it rebroadcasts the ant. To prevent flooding of the network by these broadcasts, when a node receives an ant which it had received before (that is, several ants of the same generation), it compares it with the ant with best performance. If the number of hops h and

the travel time \hat{T}_p is within the acceptance factor a_1 , then only it is rebroadcast by that node. Otherwise, the ant is discarded. An exception to this rule is made for ants which differ in the first-hop with each other. For such ants, a higher acceptance factor a_2 is used. This prevents *kite-shaped paths* (*Pseudo multiple paths*) (Di Caro, Ducatelle, & Gambardella, 2004) as shown in Figures 3 and 4.

As an ant reaches the destination d , it is converted into a backward ant. A backward ant traverses the route P in the reverse direction, updating the value of pheromone at each node. The time taken to transport data packet over P is estimated as (Di Caro, Ducatelle, & Gambardella, 2004).

$$\hat{T}_p = \sum_{i=1}^{n-1} \hat{T}_{i+1}^i \quad (3)$$

Where \hat{T}_{i+1}^i is the total time required to transfer Q (length of queue) + 1 packets to the MAC layer. This is found as (Di Caro, Ducatelle, & Gambardella, 2004)

$$\hat{T}_{i+1}^i = (Q_{mac}^i + 1) \hat{T}_{mac}^i \quad (4)$$

\hat{T}_{mac}^i is estimated as (Di Caro, Ducatelle, & Gambardella, 2004)

$$\hat{T}_{mac}^i = \alpha \hat{T}_{mac}^i + (1 - \alpha) \hat{T}_{mac}^i \quad (5)$$

where $\alpha \in [0, 1]$.

If \hat{T}_d^i is the travelling time estimated by an ant, pheromone value entry in table T^i at node i , given by

Figure 3. Pseudo multiple path (kite shaped path)³

Figure 4. Paths with 1st hop different (accepted multiple paths)⁴

T_{nd}^i is updated as (Di Caro, Ducatelle, & Gambardella, 2004)

$$\tau_d^i = \left(\frac{\hat{T}_d^i + hT_{hop}}{2} \right)^{-1} \quad (6)$$

T_{hop} is a fixed value representing single hop time in unloaded conditions. The value of T_{nd}^i is updated as (Di Caro, Ducatelle, & Gambardella, 2004)

$$T_{nd}^i = \gamma T_{nd}^i + (1 - \gamma) \tau_d^i \quad (7)$$

where $\gamma \in [0, 1]$.

Data Routing

Once the paths have been setup, routing is done *stochastically*. This means that when a node receives a data packet, it can choose to forward it to one of the several nodes in its list. A node chooses a next node from the table with a probability (Di Caro, Ducatelle, & Gambardella, 2004):

$$P_{nd} = \frac{(T_{nd}^i)^{\beta_2}}{\sum_{j \in N_d^i} (T_{jd}^i)^{\beta_2}} \quad (8)$$

If one compares Equation (8) with Equation (2), we find that, using *AntHocNet*, data packets are forwarded in a manner similar to control packets (reactive forward ant packets in this case). However, the value of β_2 is chosen much higher than β_1 so as to give preference to better paths while routing the data. On the other hand, by lowering the value of β_1 we can give liberty to reactive forward ants to be more explorative in nature.

Even though a node prefers to forward packets to a next node which lies on a better path, as the load on a network rises, the pheromone value on this particular path starts decreasing and hence the probability of selecting other paths increases. This kind of stochastic data routing leads to *automatic load balancing*.

Route Maintenance

As mentioned earlier, *AntHocNet* uses proactive route probing and maintenance. Source node unicasts proactive ants to the destination. These ants are forwarded by each node in a manner similar to the other control packets. However, they also have a small probability

of being broadcasted. Hence, an ant which reaches the destination node after selected number (say, one or two) of broadcasts finds out a fresh route to destination. If an ant is not broadcasted, it finds out fresh information regarding this route.

A node uses *hello* packets to track its neighbours. If a node finds out a new neighbour, it adds it to its routing table. However, if a node discovers that a node has moved from its neighbourhood (for example, if it does not respond to the *hello* messages), a node broadcasts its neighbour, it removes it from its routing table and broadcasts a *link failure notification*, so that the other nodes in the network update their table to include that the node does not have a route to the destination any more.

If, however, the node realizes that the problem is due to link failure and not node movement, it tries to repair the path by initiating a *route repair ant* to the destination. This ant tries to find an alternate path to the destination and if it does not return within a specified time, the node assumes a failure, and broadcasts *link failure notification*.

CONCLUSION

This chapter presents an example of how ACO techniques can be applied to solve problems in ad-hoc networks. We first introduced the food foraging behaviour of ants and explain the phenomenon using the concept of pheromone. We then explained the concept of artificial ants and other ACO techniques and explain the *random probability rule*.

We, then, introduce the *AntHocNet* algorithm (Di Caro, Ducatelle, & Gambardella, 2004) that uses ACO techniques, for routing in mobile ad-hoc networks. We explained how different routes are discovered using *reactive forward ants*. We also explained how *random probability rule* is used in the case of *AntHocNet*. We then presented how data can be routed stochastically using these routes and the *automatic load-balancing* that it achieves. In the end, we explained how these routes are maintained using *hello packets* and *link failure notification*.

KEY TERMS

Ant Colony Optimization: Ant Colony Optimization involves a set of algorithms modelled on the foraging behaviour of a colony of natural ants.

AntHocNet: An Ant Colony Optimization-based algorithm for routing in ad-hoc networks using reactive route set up combined with proactive route probing, maintenance and improvement.

Heuristic Information: Static value associated with a solution that represents the relative suitability of a solution among its peers based on intuition, previous experience or common sense.

Pheromone: Chemical secreted by natural ants, the presence of which is an indicative of the number of ants that have followed a particular path. This chemical is modelled to represent the historical preference that is associated with a path in Ant Colony Optimization.

Proactive Forward Ant: Control ant agents that are unicast to destination node and are responsible for finding fresh information about existing routes or to find fresh nodes to the destinations.

Reactive Forward Ant: Ant agents responsible for discovering paths to the destination nodes.

Stigmergy: Method of indirect communication between simple agents by altering their environment. Ants use a chemical called Pheromone to communicate with each other, which is an example of stigmergy.

Swarm Intelligence: Group of bio-inspired algorithms which is modelled on the collective behaviour of a group of social organisms such as ants, termites, bees, fishes and birds.

Swarm Robotics

Amanda J.C. Sharkey

University of Sheffield, UK

INTRODUCTION

Swarm Robotics is a biologically inspired approach to the organisation and control of groups of robots. Its biological inspiration is mainly drawn from social insects, but also from herding and flocking phenomena in mammals and fish. The promise of emulating some of the efficient organisational principles of biological swarms is an alluring one. In biological systems such as colonies of ants, sophisticated cooperative behaviour emerges despite the simplicity of the individual members, and the absence of centralised control and explicit directions. Such societies are able to maintain themselves as a collective, and to accomplish coordinated actions such as those required to construct and maintain nests, to find food, and to raise their young. The central idea behind swarm robotics is to find similar ways of coordinating and controlling collections of robots.

BACKGROUND

The mechanisms that underlie social insect behaviour have inspired an approach that emphasises autonomy, emergence and distributed functioning, and avoids a reliance on centralised control and communication. This approach underlies both swarm robotics, and the closely related notion of artificial “swarm intelligence”. The term “swarm intelligence” was first coined in the context of cellular robotic systems, on the basis of the features that the simulated robotic collections shared with social insects: namely “decentralised control, lack of synchronicity, simple and (quasi) identical members” and size (Beni and Wang, 1989). Bonabeau et al (1999) describe as swarm intelligence, “any attempt to design algorithms or distributed problem-solving devices inspired by the collective behaviour of social insect colonies and other animal societies” (pg 7, Bonabeau et al, 1999). The key ingredients of swarm intelligence that they emphasise are self-organisation, and stigmergy,

(indirect communication via the environment). Martinoli (2001) similarly describes the swarm intelligence approach as emphasising “parallelism, distributedness, and exploitation of direct (agent-to-agent) or indirect (via the environment) local interactions among relatively simple agents.

Swarm robotics has been described as the application of swarm intelligent principles to collective robotics (Sharkey and Sharkey 2006). The same principles of decentralised local control and communication are applied to physically instantiated robots. In swarm robotics, the emphasis is on using a number of simple robots that are autonomous, not subject to global control, and that have limited communication abilities. The reliance on local communication means that the potential problems of communication bottlenecks, or centralised failure, are avoided. The system benefits from the redundancy of using several robots: if individual robots were to fail, others could take over, and new ones could be added without the need for recalibration of communicative systems. In the same way, the activities of an ant colony need not be affected by the removal of some of its members. The simplicity of the individual robots means that they are able to respond quickly to the environment. There are also several tasks, such as exploring an environment, that can be accomplished more efficiently if a number of robots are used.

Of course, using a collection of robots creates some new problems itself (Bonabeau et al, 1999). There is the possibility of stagnation: without global knowledge, a group of robots can find themselves in a deadlock situation. Too many robots trying to reach the same location, or perform the same task could obstruct each other. Another problem is finding a solution to a task: how can situations be engineered in order that a desired solution can emerge? Nonetheless, the promise of being able to send a number of autonomous robots to perform a task, particularly in sites that are remote and inhospitable to humans, outweighs the disadvantages.

SWARM ROBOTICS

Early work in swarm robotics can be illustrated by describing a series of studies in which simple robots are shown to be able to collect a number of objects in one place, and even to sort them. This work was initiated by a paper by Deneubourg et al (1991), and observations of the ability of ants to work together to sort their brood into clusters of eggs, larvae and cocoons, despite the insects' limited communicative abilities. In their simulations, "ant-like robots" (ALRs) moved randomly in a two dimensional environment populated by objects, and showed a greater probability of picking up the isolated items they encountered, and a greater probability of dropping them at locations where more items of that type are present. Their simulations demonstrated that the model eventually resulted in clustering and sorting of objects. Beckers et al (1994) applied these ideas to actual robots. Their robots had IR sensors for obstacle avoidance, a gripper to pick up the objects, and a microswitch that was activated when they pushed three pucks or more. They could (i) travel in a straight line until (ii) an obstacle was detected, whereupon they would turn to avoid it, or (iii) until their micro switch was activated, whereupon they would drop the pucks they were carrying, and turn away. Since the robots' grippers would automatically collect up pucks they encountered, these behaviours were sufficient to result in the eventual collection of all the objects in a single cluster. Holland and Melhuish (1999) extended these results: augmenting the robots' behaviours with a "pull-back" rule that required robots to pull pucks of one colour back for some distance before releasing them. Its effect was that (after several hours), pucks scattered across the arena were collected up by the robots, and sorted into clusters of different colours. More recently, Wilson et al (2004) reported further investigations of different minimalist solutions to 'ant-like annular sorting' using simple robots and simple mechanisms.

Other swarm robotic studies have also explored the behaviours that can be accomplished by robots that respond in a fixed manner to environmental stimuli, and that do not directly communicate with each other. A number of studies were designed to investigate explicitly cooperative tasks, (tasks that have been designed to require cooperation), such as pushing a box that is too heavy to be pushed by a single robot (Kube and Zhang, 1996; Kube and Bonabeau, 2000). Stick pulling

(Ijspeert et al, 2001) is a similarly explicitly cooperative task that involved locating sticks in a circular arena and pulling them out of the ground in circumstances where the length of the stick means that a single robot cannot pull it out by itself, but must collaborate with a second robot. Ijspeert et al (2001) used reactive robots with minimal sensing abilities. Their results show that collaboration can still be obtained despite the absence of signalling, planning, or direct communication.

These studies share a number of features. They all involve a number of robots. The robots are autonomous, and not controlled centrally; the control methods used could be scaled up to larger numbers of robots, or scaled down to smaller numbers since each robot performs a set number of fixed behaviours in response to certain stimuli. The individual robots are certainly simple – they have no knowledge of the environment they are in, or even of the other robots in it. They are essentially reactive: they have no knowledge or map of their environment, and they have no ability to communicate directly with other robots, or to receive instructions. Nonetheless, they exhibit apparently co-operative behaviour. Many of the studies make use of the concept of stigmergy, a term introduced by Grassé (1959) in the context of his observations of termite building behaviour. He noted that termite workers were stimulated to further constructive activity in the presence of particular features of a construction. The behaviour of the termite is affected by changes in the environment created either by itself, or by other termites: a form of indirect communication, where environmental changes have a signalling function. All of the examples discussed here explicitly draw analogies and parallels to living biological systems. Together, they illustrate some of the potential of swarm robotics: despite the simplicity of the individual robots, their interactions with the environment result in the performance of tasks in the physical world, and demonstrate that cooperation between such simple entities can emerge in the absence of any planning, centralised coordination, or even any direct communication between the robots.

Nonetheless, as research in swarm robotics has developed, so has a certain lack of clarity and agreement about the terms to be used and about what their defining features are (see also Dorigo and Sahin, 2004). There is agreement that swarm robotics implies the use of control and communication methods that are decentralised and scalable, so that communication bottlenecks are avoided, the robots operate autonomously, and the

same approach could be applied unchanged to varying sizes of robot collection. It is less clear whether swarm robotics necessarily implies the use of reactive control and constraints on the kinds of communication involved. Bonabeau et al (1999) suggest that swarm-based robotics may be “loosely defined” as “reactive collective robotics” (pg 19), and that “swarm-based robotics relies on the anti-classical AI idea that a group of robots may be able to perform tasks without explicit representations of the environment and of the other robots”. Should swarm robotics be restricted to the use of robots with such minimal representational abilities?

Arguments in favour of restricting swarm robotics to the use of reactive robots can be made on the basis of parsimony. Pfeifer and Scheier (2001) argue that a more parsimonious model should be preferred over more complicated ones, and that, for instance, a model that can explain “*the clustering behaviour of ants based on simple reflexes, for example, is to be preferred over one that postulates some sort of internal representation of clustering*”. Of course, there are practical advantages to be gained from attempting to accomplish a given task with the simplest possible mechanism. Minimalist unit design and a reliance on reactive robots that respond rapidly to stimuli in the environment can facilitate a rapid response to changing situations, and lead to the use of robots that are relatively cheap and expendable. Wilson et al (2004) for example, provide a practical justification for their minimalist approach that relies on robots built from simple mechanical components and sensors, claiming, “*Potentially, this allows for the production of more robust and cheaper robot units.... Simple behavioural rules are employed so the robots are less complex. Rules have to be embodied and realized in a machine, and the more complicated the rules, the more complicated the hardware and software in the machine is likely to be. The more complicated the hardware and software required, the more there is to go wrong.*” The problem is that there is likely to be a limit to the number and kinds of task that can be accomplished using reflexive behaviours, and avoiding internal representation.

Another reason for an emphasis on reactive robots in swarm robotics is based on its inheritance from behaviour-based robotics. Rodney Brooks and his associates introduced the idea of behaviour-based robotics, and the advantages to be gained from departing from the traditional emphasis on reasoning and representation in Artificial Intelligence (Brooks 1999). They showed

that certain tasks could be solved more easily by robots that were situated in the world, and could react to and exploit characteristics of the environment, than by robots such as Shakey (Nilsson, 1984) that depended on a representationally intensive, and slow approach to modelling the world. However, again the range of tasks to which robots without representations can be applied is limited, and more recent formulations of behaviour-based robotics (Mataric 1997) incorporate the idea of action-centred representations.

A final reason for preferring to use reactive robots in swarm robotics can be found in assumptions about the limited abilities of the social insects that inspire them. Debates over parsimonious explanation have always occurred in biology. For instance, Griffin (1992) has argued that there has been a long held view that social insects are little more than “genetically programmed clockwork”. Under such a view, insects can only react to stimuli, and are not able to represent the world, or to communicate amongst themselves. This view of insects as clockwork (albeit clockwork with sensors that enable it to respond to the world) is one that can be traced back to behaviourism’s response to the anthropomorphism that preceded it. The synopsis of a book on insect learning (Papaj and Lewis, 1992) claims that “until recently, insects were viewed as rigidly programmed automatons: now however, it is recognised that they can actually learn and that their behaviour is plastic”.

There is a gradually accumulating body of evidence that shows that social insects do have some representational and learning abilities, and that their communicative abilities are more extensive than was once supposed. For example, Collett and Collett (2002) review evidence for memory use in insect visual navigation, describing evidence that shows reliable recognition of visual landmarks, and reliable performance of learned routes. Franks and Richardson (2006) report evidence that the ant *Temnothorax albipennis* can use tandem running to lead another ant from nest to food, and make use of bi-directional feedback, as the leader ant modifies its behaviour when being followed – the leader teaches the route to the follower. Robinson et al (2005) have shown that as well as laying a pheromone trail to guide others to a food source, Pharaoh’s ants can also lay a negative “no entry” signal to mark an unrewarding trail path.

Such findings could justify extending the capabilities of individual robots in a swarm beyond those of

reactive control. Robots with some ability to learn a route, to recognise landmarks, or to keep track of the number of encounters they have with others would be able to perform a wider range of tasks. It would be interesting to explore the ways in which such abilities could be incorporated into swarm robotics. An approach of “biologically plausible minimalism”, in which the representational and communicative abilities of the robots were restricted to those plausible for social insects would ensure that any such approach still preserved the swarm advantages of decentralisation and scalability shown in their biological counterparts.

FUTURE TRENDS

An avenue that could be explored in future swarm robotic research is that of incorporating simple forms of memory and representational ability, without compromising the swarm-related benefits of local control and communication and scalability. Relatively simple robots could, for instance, be given some minimal representational abilities: the ability for instance to learn a route, or to recognise landmarks. Similarly, it would be interesting to explore the use of some further communicative abilities other than that of pheromone trail laying. For example, robots could be given the ability to convey, and to sense, the tasks that they and other robots are involved in, and to keep account of the frequency of their encounters. This would enable some distributed decision making abilities, and dynamic switching between tasks based on their local records of the numbers performing each task. These limited cognitive abilities would still depend on entirely local control, and would be scalable, but such extensions could be used to extend the range and complexity of tasks to which swarm robotics could be applied.

CONCLUSION

In this article, we have surveyed swarm robotics research and discussed the source of its biological inspiration – the self-organised behaviour of social insects. Some representative studies have been described, and their common characteristics noted. These include the ideas that the robots in a swarm should be simple, autonomous, and subject to local control and communication. The expected benefits of using such robots are that they

should be able to provide a robust and flexible solution for practical applications in inaccessible areas; one that benefits from an inherent redundancy, since robots could fail or be replaced without the need for recalibration of the control and communication methods.

The approach is of interest, but still in its early stages. There is still some disagreement about the use of the term ‘swarm robotics’, and the constraints it implies. In particular, it is not clear whether swarm robotics necessarily involves the use of reactive robots with effectively no representational ability. There are reasons to prefer the simplest possible solution for a given task, but the argument is made here that there is evidence that social insects do have some ability to represent the environment, and that incorporating such abilities into swarm robotics would extend the range of tasks to which the approach could be applied, without compromising its swarm-related advantages.

KEY TERMS

Behaviour-Based Robotics (BBR): A paradigm initiated by Brooks (1999) that stressed the importance of studying robots situated in the world, and responding to information directly gathered by their sensors. BBR robots make minimal use of internal representations.

Emergent Behaviour: Results from the unsupervised interaction of a number of simpler processes. The complex behaviour of an ant colony is a good example of emergent behaviour: the individual ants carry out their tasks on a local level, but the combined effect is of a colony that is able to maintain its own organisation.

Reactive Robotics: An approach to robot control in which there is a direct mapping from the sensor input to the robot, and its motor output. No use is made of internal representations of the world. The approach dates from the reactive robots developed by Grey Walter (1954).

Self-Organisation: Pattern-formation processes in physical and biological systems that occur as a result of

interactions internal to the system, without intervention by external influences.

Stigmergy: A method of indirect communication that occurs when one individual modifies the environment, and another responds to that environment at a later time.

Swarm Intelligence: Describes attempts to design algorithms and to solve problems, using methods inspired by observations of the collective behaviour of biological groups such as insect colonies.

Social Insects: Insects that live cooperatively in colonies and exhibit a division of labour among distinct castes. E.g. termites, ants, bees, some wasps.

Symbol Grounding Problem

INTRODUCTION

The topic of representation acquisition, manipulation and use has been a major trend in Artificial Intelligence since its beginning and persists as an important matter in current research. Particularly, due to initial focus on development of symbolic systems, this topic is usually related to research in symbol grounding by artificial intelligent systems. Symbolic systems, as proposed by Newell & Simon (1976), are characterized as a high-level cognition system in which symbols are seen as “[lying] at the root of intelligent action” (Newell and Simon, 1976, p.83). Moreover, they stated the Physical Symbol Systems Hypothesis (PSSH), making the strong claim that “a physical symbol system has the necessary and sufficient means for general intelligent action” (p.87).

This hypothesis, therefore, sets equivalence between symbol systems and intelligent action, in such a way that every intelligent action would be originated in a symbol system and every symbol system is capable of intelligent action. The symbol system described by Newell and Simon (1976) is seen as a computer program capable of manipulating entities called symbols, ‘physical patterns’ combined in expressions, which can be created, modified or destroyed by syntactic processes. Two main capabilities of symbol systems were said to provide the system with the properties of closure and completeness, and so the system itself could be built upon symbols alone (Newell & Simon, 1976). These capabilities were designation – expressions designate objects – and interpretation – expressions could be processed by the system. The question was, and much of the criticism about symbol systems came from it, how these systems, built upon and manipulating just symbols, could designate something outside its domain.

Symbol systems lack ‘intentionality’, stated John Searle (1980), in an important essay in which he de-

scribed a widely known mental experiment (*Gedankenexperiment*), the ‘Chinese Room Argument’. In this experiment, Searle places himself in a room where he is given correlation rules that permits him to determine answers in Chinese to question also in Chinese given to him, although Searle as the interpreter knows no Chinese. To an outside observer (who understands Chinese), the man in this room understands Chinese quite well, even though he is actually manipulating non-interpreted symbols using formal rules. For an outside observer the symbols in the questions and answers do represent something, but for the man in the room the symbols lack intentionality. The man in the room acts like a symbol system, which relies only in symbolic structures manipulation by formal rules. For such systems, the manipulated tokens are not about anything, and so they cannot even be regarded as representations. The only intentionality that can be attributed to these symbols belongs to who ever uses the system, sending inputs that represent something to them and interpreting the output that comes out of the system. (Searle, 1980)

Therefore, intentionality is the important feature missing in symbol systems. The concept of intentionality is of *aboutness*, a “feature of certain mental states by which they are directed at or about objects and states of affairs in the world” (Searle, 1980), as a thought being about a certain place.¹ Searle (1980) points out that a ‘program’ itself can not achieve intentionality, because programs involve formal relations and intentionality depends on causal relations. Along these lines, Searle leaves a possibility to overcome the limitations of mere programs: ‘machines’ – physical systems causally connected to the world and having ‘causal internal powers’ – could reproduce the necessary causality, an approach in the same direction of situated and embodied cognitive science and robotics. It is important to notice that these ‘machines’ should not be just robots controlled

by a symbol system as described before. If the input does not come from a keyboard and output goes to a monitor, but rather came in from a video camera and then out to motors, it would not make a difference since the symbol system is not aware of this change. And still in this case, the robot would not have intentional states (Searle 1980).

Symbol systems should not depend on formal rules only, if symbols are to represent something to the system. This issue brought in another question, how symbols could be connected to what they represent, or, as stated by Harnad (1990) defining the Symbol Grounding Problem:

“How can the semantic interpretation of a formal symbol system be made intrinsic to the system, rather than just parasitic on the meanings in our heads? How can the meanings of the meaningless symbol tokens, manipulated solely on the basis of their (arbitrary) shapes, be grounded in anything but other meaningless symbols?”

The Symbol Grounding Problem, therefore, reinforces two important matters. First that symbols do not represent anything to a system, at least not what they were said to ‘designate’. Only someone operating the system could recognize those symbols as referring to entities outside the system. Second, the symbol system cannot hold its closure in relating symbols only with other symbols; something else should be necessary to establish a connection between symbols and what they represent. An analogy made by Harnad (1990) is with someone who knows no Chinese but tries to learn Chinese from a Chinese/Chinese dictionary. Since terms are defined by using other terms and none of them is known before, the person is kept in a ‘dictionary-go-round’ without ever understanding those symbols.

The great challenge for Artificial Intelligence researchers then is to connect symbols to what they represent, and also to identify the consequences that the implementation of such connection would make to a symbol system, e.g. much of the descriptions of symbols by means of other symbols would be unnecessary when descriptions through grounding are available. It is important to notice that the grounding process is not just about giving sensors to an artificial system so it would be able to ‘see’ the world, since it ‘trivializes’ the symbol grounding problem and ignores the important

issue about how the connection between symbols and objects are established (Harnad, 1990).

BACKGROUND

The symbol grounding problem aroused from the notice that symbol systems manipulated structures that could be associated with things in the world by an observer operating the system, but not by the system itself. The quest for symbol grounding processes is concerned with understanding processes which could enable the connection of these purely symbolic representations with what they represent in fact, which could be directly, or by means of other grounded representations.

This represents a technological challenge as much as a philosophical and scientific one, but there is a strong interrelation between them. From one side there is the concern with the technological design and engineering of symbol grounding processes in artificial systems. On the other side, the grounding process is a process present in natural systems and therefore precedes artificial systems. Theories and models are developed to explain grounding and if consistent and detailed enough may in principle be implemented in artificial systems, which in return correspond to a laboratory for these theories, when their hypothesis are tested and new questions are raised, allowing further refinement and experimentation.

A first proposal for symbol grounding as made by Harnad (1990) in the same paper where he gave a definition for the ‘symbol grounding process’. Harnad proposed that symbolic representations should be grounded bottom-up by means of non-symbolic representations: iconic representations – sensory projections of objects – and categorical representations – invariant features of objects. Neural networks were pointed out as a feature learner and discriminator, which could link sensory data with symbolic representations, after been trained to identify the invariant features. This would causally connect symbols and sensory data, but this proposal describes just a tagging system that gives names to sensed objects but does not use this to take actions and interact with its environment. A ‘mental theater’ is formed as Dennett (1991) defined, where images are projected internally and associated with symbols, but no one is watching it. Besides the symbols and the iconic representations are probably given by the systems operator and the system must learn them

all, making no distinction between them and attributing no functionality to them.

Another approach to deal with the limitation of symbol systems was presented by Brooks (1990). Instead of modeling artificial systems as symbol systems, Brooks rejected the symbolic approach for cognition modeling and the need of representations for this end: “[r]epresentation is the wrong unit of abstraction in building the bulkiest parts of intelligent systems” (Brooks, 1991b, p.139), with representations seen as centralized, explicit and pre-defined structures. He proposed the Physical Grounding Hypothesis (Brooks, 1990), supporting that intelligent systems should be embedded in the real world, sensing and acting in it, establishing causal relations with perceptions and actions, being built in a bottom up manner with higher levels depending on lower ones. There was no need for representations because the system is already in touch with the objects and events it would need to represent. Moreover, Brooks called up attention that the most important aspect of intelligence was left out: to deal with the world and its dynamics. Instead of dealing with sophisticated high-level processes dealing with simple domains, research in the so-called Nouvelle AI should focus in simpler processes dealing with greatly complicated domains (such as the real world) and work its way from there to higher level ones (Brooks, 1990). Brooks (1991a) also stated principles to this new approach, such as situatedness and embodiment, which are the mottos of the situated and embodied cognition studies (Clark, 1997).

Symbolic representations are in fact not incompatible with the Physical Grounding Hypothesis and with the Situated and Embodied Cognition approach. Brooks (1990) himself pointed out high-level abstractions should be made ‘concrete’ by means lower-level processes, thus symbolic representations should be causally constructed from the situated/embodied interaction dynamics through the artificial agent’s history. This approach was followed by several researchers dealing with symbol grounding when building artificial systems in which representations emerge from agent’s interactions, when learning processes take place (e.g. Ziemke 1999, Vogt 2002, Cangelosi 2002, Roy 2005; see also Christiansen & Kirby 2003; Wagner, 2003, for a review of experiments about language emergence).

In most of these new systems, artificial agents are situated in an environment, in which they can sense and act, and are allowed to interact with other agents

– either artificial or biological ones. By means of associative learning mechanisms, agents are able to gradually establish relations between representations and what they represent in the world, using communication as the basis to guide this learning process. And remarkably, when explicitly discussing the ‘symbol grounding problem’ (Vogt 2002, Cangelosi et al. 2002, Roy 2005), the sign theory of Charles Sanders Peirce, particularly his definition of a symbol, is brought forth as the theoretical background for a new view into this problem.

SEMIOTICS AND SYMBOL GROUNDING PROBLEM

The symbol grounding problem is fundamentally a matter of how certain things can represent other things to someone. Although symbol systems were said to have ‘designation’ properties (Newell & Simon, 1976), which would allow symbols manipulated by the system to stand for objects and events in the world, this property should actually be attributed to an outside observer who was the only one able to make this connection. The artificial system itself did not have this capability, so the symbols it manipulated were said to be ungrounded. Building artificial systems based on the hypothesis that symbolic processes were autonomous and no other process was required proved to be flawed, and the quest to understand representation processes came up as a major issue.

Representation is the focus of semiotics, the ‘formal science of signs’ as defined by Charles Sanders Peirce. His definition of Semiotics and his pragmatic notion of meaning as the ‘action of signs’ (semiosis), have had deep impact in philosophy, psychology, theoretical biology, and cognitive sciences. Sign model and classification was developed by Peirce from his logical-phenomenological categories. His definition of a sign as “something which stands to somebody for something in some respect or capacity” (Peirce 1931-1958, §2.228) interrelates three distinct elements: a sign, an object, which the sign represents in some respect, and an effect (interpretant) on an interpreter. The nature of the relation between sign and object establishes the ‘most fundamental division of signs’: signs can either be icons, indexes or symbols. Icons stand for the object through resemblance or similarity, since it carries properties in common with the object. The drawing

of an object, a diagram and 'sensory projections' are regarded as icons. Indexes establish spatio-temporal physical relation with its object, both occur as events and the interpreter is not responsible for connection between them, he just remarks it when it is established (Peirce 1931-1958, §2.299). Examples of indexes are smoke, which is related with fire, a scream that calls up our attention, or a bullet hole. According to Peirce, a symbol is a sign because it is interpreted as such, due to a natural or conventional disposition, in spite of the origin of this general interpretation rule (Peirce 1931-1958, §2.307). A word, a text and even a red light in a traffic light alerting drivers to stop are symbols. In this symbolic process, the object which is communicated to the interpretant through the sign is a lawful relationship between a given type of sign and a given type of object. Generally speaking, a symbol communicates a law to the interpretant as a result of a regularity in the relationship between sign and object.

Furthermore, it is important to remark that symbols, indexes and icons are not mutually exclusively classes; they are interrelated and interdependent classes. "A Symbol is a law, or regularity of the indefinite future. [...] But a law necessarily governs, or "is embodied in" individuals, and prescribes some of their qualities. Consequently, a constituent of a Symbol may be an Index, and a constituent may be an Icon" (Peirce 1931-1958, §2. 293). Symbols require indexes which require icons. Harnad (1990) already noticed that symbols need non-symbolic representations and proposed that symbols are to be connected with sensory projections and categorical features, both regarded as icons in Peirce's theory. A symbol is a sign and as such it involves an object which it refers to and an interpretant, the effect of the sign, so a symbol can only represent something to someone and when someone is interpreting it. A symbol distinguishes itself from other signs since it holds no resemblance or spatial-temporal relation with the object and thus depends on a general rule or disposition from the interpreter. At last, symbols incorporate indexes (and icons, consequently) and one way symbols can be acquired is by exploiting indexical relations between signs and objects, establishing regularities between them.

FUTURE TRENDS

The discussion around the symbol grounding problem has an important component of theoretical aspects since it involves issues such as representation and cognitive modeling. Nevertheless, it is also a technological concern if researchers in Artificial Intelligence intend to model and build artificial systems which are capable of handling symbols in the appropriate way. The most evident consequence of discussion the problem of symbol grounding and ways of solving it is related to language and more generally with communication systems between agents (artificial ones or not). If we expect a robot to act appropriately when we say 'bring me that cup', we should expect it to know what these symbols represent so it will act accordingly. Moreover, we expect an artificial agent to learn and establish symbol-object connections autonomously, without the need of programming everything prior to the robot execution or reprogram it every time a new symbol is to be learned.

The employment of strong theoretical basis that describes thoroughly the process of interest can certainly contribute to the endeavor of modeling and implementing it in artificial systems. The semiotics of Charles S. Peirce is recognized as a strongly consistent theory, and has been brought forth by diverse researchers in Artificial Intelligence, though fragmentally. We expect that Peirce description of sign processes will shed light on the intricate problem of symbol grounding. Particularly, Peirce conception of meaning as sign action can open up perspectives on the implementation of semiotic machines, which can produce, transmit, receive, compute, and interpret signs of different kinds, meaningfully (Fetzer 1990). According to the pragmatic approach of Peirce, meaning is not an infused concept, but a power to engender interpretants (effects on interpreters). According to Peirce's pragmatic model of sign, meaning is a, context-sensitive (situated), interpreter-dependent, materially extended (embodied) dynamic process. It is a social-cognitive process, not merely a static system. It emphasizes process and cannot be dissociated from the notion of a situated (and actively distributed) communicational agent. It is context-sensitive in the sense that is determined by the network of communicative events within which the interpreting agents are immersed with the signs, such that they cooperate with one another. It is both interpreter-dependent and objective because it

triadically connects sign, object, and an effect in the interpreter.

CONCLUSION

The original conception of artificial intelligent systems as symbols systems brought forth a problem known as symbol grounding problem. If symbol systems manipulate symbols, these symbols should represent something to the system itself and not only to an external observer, but the system has no way of grounding these symbols in its sensory and motor interaction history, since it does not have one. Many researchers pointed this key flaw, particularly John Searle (1980) with his Chinese Room Argument and Stevan Harnad (1990) with the definition for the problem became well know.

A direction towards modeling artificial systems as embodied and situated agents instead of symbol manipulating systems was pointed out, urging the need to implement systems that could autonomously interact with its environment and with the things it should have representations for. But the topic of symbol grounding also needs a description of how certain things come to represent other things to someone, the topic of study of semiotics. The semiotics of C.S. Peirce has been used as theoretical framework in the discussion the topic of symbol grounding problem in Artificial Intelligence. The application of his theory in dealing with the symbol grounding problem should further contribute to the development of computational models of cognitive systems and to the construction of ever more meaningful machines.

KEY TERMS

Icon: A sign that represents its object by means of similarity or resemblance.

Index: A sign spatial-temporally (physically) connected with its object.

Representation: The same as a sign.

Sign: Something that stands for something else in a certain aspect to someone.

Symbol: A sign that stands for its object by means of a law, rule or disposition.

Symbol Grounding Problem: The problem related to the requirement of symbols to be grounded in something else than other symbols, if a symbol is to represent something to an artificial system.

Symbol Systems: A system that models intelligent action as symbol manipulation alone.

Symbolic Search

Stefan Edelkamp

University of Dortmund, Germany

INTRODUCTION

Symbolic search solves state space problems consisting of an initial state, a set of goal states, and a set of actions using a succinct representation for state sets. The approach lessens the costs associated with the exponential memory requirements for the state sets involved as problem sizes get bigger.

Symbolic search has been associated with the term *planning via model checking* (Giunchiglia and Traverso 1999). While initially applied to *model check* hardware verification problems (McMillan 1993), symbolic search features many modern *action planning* systems (Ghallab et al. 2000).

Symbolic search algorithms explore the underlying problem graph by using functional expressions to represent sets of states and actions. Compared with the space requirements induced by standard explicit-state search algorithms, symbolic representations additionally save space by sharing parts of the state vector. Algorithm designs change, as not all search algorithms adapt to the exploration of state sets.

BACKGROUND

Binary decision diagrams or BDDs are one option for a space-efficient representation for state sets.

A BDD (Bryant 1992; see Figure 1), is a data structure to manipulate Boolean functions efficiently. BDDs

are finite state machines over the alphabet $\{0,1\}$ with a 1-sink that operates as an accepting state. Each internal node is labelled with the variable (index) for selecting the outgoing transition (either 1 or 0, see figure) for a given variable assignment. For evaluating a BDD, a path is traced from the root to the sinks (all paths obey the same variable ordering). What distinguishes BDDs from decision trees is the use of reduction rules, detecting unnecessary variable tests and repeating subgraphs. This leads to a unique representation, polynomial in the number of input variables for many interesting functions. The reduced and ordered BDD representation is unique; a clear benefit to the satisfiability test for Boolean formulas, which by the virtue of Cook's Theorem (1971) is an NP-hard problem

In symbolic search, BDDs accept the state vector representation. According functions are satisfied, if the state vector for the input assignment is a member of the represented set. The characteristic function can be identified with the state set it represents.

The transition relation *Trans* represents the actions (see Figure 2). It refers to current state variables x and next state variables x' and is satisfied, if there is an action that transforms a state vector into one of its successors. The transition relation for the entire prob-

Figure 1.

Figure 2.

lem decomposes in the disjunction of the transition relations for singleton actions. The order of variables in the state vector is crucially influencing the size of the BDD. Unfortunately, the problem of finding the ordering that minimizes the BDD size is NP-hard (Wegener 2000). The interleaved representation for the $\text{Trans}(x, x')$ that alternates between x and x' variables often leads to small BDDs.

The image of a state set States wrt. the transition relation Trans is computed as $\text{Image}(x') := \exists x (\text{Trans}(x, x') \wedge \text{States}(x))$, where x and x' are vectors of Boolean state variables. The result of this image operation is a characteristic function of all states reachable from States in one step. In order to repeat the process, x with x' have to be substituted for the next iteration by computing the *relational product* $\text{States}(x) := \exists x' ((x = x') \wedge \text{Image}(x'))$. In an interleaved variable ordering with alternating indices for x and x' , this operation reduces to a mere textual replacement of node labels.

SYMBOLIC SEARCH ALGORITHMS

State space problems numbers of finite domain can be encoded via atomic propositions. A binary encoding is more efficient than a unary one such that most BDD libraries include finite domain variable support. For basic calculus, relations are pre-computed. For example, the binary relation $\text{Inc}(a, b)$ for $a+1=b$ is the disjunction of all possible value assignments of a to j and all possible value assignments of b to $j+1$ for all j counted from 1 to the domain size minus 1. For constructing the ternary relation $\text{Add}(a, b, c)$, denoting $a+b=c$, the enumeration of all possible assignments for a , b and c is less efficient than computing the term $\text{Add}(a, b, c) := (b=0 \wedge a=c) \vee \exists b', c' (\text{Inc}(b', b) \wedge \text{Inc}(c', c) \wedge \text{Add}(a, b', c'))$ recursively. Starting with the first clause the second clause is applied until convergence.

Symbolic Breadth-First Search

In iteration i of the symbolic variant of breadth-first-search the set of states $\text{States}[i]$ reachable from the initial state s in i steps is computed. The search is initialized with $\text{States}[0]$ set to the initial state set. In order to terminate the search the algorithm checks, whether or not a state is represented in the intersection of the set $\text{States}[i]$ with the set of goal states. Since $\text{States}[0], \dots, \text{States}[i-1]$ have been computed without

success, given a non-empty intersection, i is the optimal solution length. To avoid an infinite search behaviour in case of the absence of a solution, $\text{Reach} = \text{States}[0] \vee \dots \vee \text{States}[i-1]$ is omitted from $\text{States}[i]$ by setting $\text{States}[i] := \text{States}[i] \wedge \neg \text{Reach}$ before updating $\text{Reach} := \text{Reach} \vee \text{States}[i]$. For some problem classes (like undirected or acyclic graphs) the *duplicate elimination scope* $\{0, \dots, i-1\}$ can be reduced to a limited number of breadth-first search levels.

By keeping the intermediate BDDs contained in the memory, a legal sequence of states linking the initial state to any goal state g in $\text{States}[i] \cap G$ is a successful solution. The state on an optimal path to a goal g in layer i must be located in the second last breadth-first search layer $i-1$. All states that are contained in the intersection of the predecessors of the goal g are and $\text{States}[i-1]$ are reachable in an optimal number of steps and reach the goal in one step. Any of these states can be chosen to continue *solution reconstruction*. Eventually the initial state is found. If layers have been eliminated to recover main memory, divide-and-conquer solution reconstruction methods are required (Jensen et al. 2006). Variants of symbolic breadth-first search compute cost-optimal solutions subject to general cost functions (Edelkamp 2006).

Backward breadth-first search exploits the relational representation for the actions to compute the *preimage* according to the formula $\text{Preimage}(x) := \exists x' (\text{States}(x') \wedge \text{Trans}(x, x'))$. Consequently, the search starts with the goal state set and iterates until it hits the start state. Bidirectional symbolic breadth-first search executes concurrent iterations of forward and backward breadth-first search until the two search frontiers meet.

Symbolic Dijkstra's Single Source Shortest Paths Algorithm

Action costs are a natural search concept. In many applications, costs can only be bounded integers. Examples for such discrete cost actions are *macros* as exploited in the macro-problem solver by Korf (1985).

Let the *weighted transition relation* $\text{Trans}(c, x, x')$ evaluate to 1, if the step from x to x' has cost $c \in \{1, \dots, C\}$, encoded in binary. The symbolic version of Dijkstra's single-source shortest paths algorithm (1959) then works as follows. The priority relation $\text{Queue}(f, x)$ is initialized with the representation of the start state and f -value 0. Until a goal state is reached, in each iteration, the algorithms determines the minimum f -value

min, the relation $\text{Min}(x)$ of all states in the priority queue with value min, and the relation $\text{Rest}(f,x)$ of the remaining set of states $\text{Queue}(f,x) \setminus \text{Min}(x)$. The transition relation $\text{Trans}(c,x,x')$ is then applied to Min to determine the relation for the successor state set. To attach the new values $f=\text{min}+c$ to this set, relation Add mentioned above applies. Finally, the priority relation for the next iteration is obtained by intersecting the evaluated successor set with the remaining queue. The algorithm mimics the execution of Dijkstra's algorithm on 1-level bucket data structure (Dial 1969). As f increases monotonically, the first goal extracted from the priority queue has optimal cost.

Symbolic Pattern Databases

State space abstraction is the key aspect for the automated design of search heuristics. Applying abstractions simplifies a problem, and exact distances in relaxed problems then serve as lower bound for the concrete base-level search. Proper abstractions preserve path existence. *Pattern databases*, introduced by Culberson and Schaeffer (1998), completely evaluate the abstract search space prior to the concrete search. The limitation for applying pattern databases in search practice is the restricted amount of (main) memory.

More than one pattern database can be combined by either taking the maximum (always applicable), or the sum of individual pattern database entries (only applicable if the pattern databases are disjoint). Disjoint pattern databases (Korf and Felner 2002) belong to the best known techniques to construct effective search heuristics. In order to select patterns automatically, Edelkamp (2000) as well as Haslum et al. (2005) use greedy *pattern packing* to divide the state vector into disjoint parts for constructing pattern databases that respect a pre-specified memory limit.

Symbolic pattern databases (Edelkamp 2002) are functional pattern databases for later use either in symbolic or explicit-state heuristic search. Different to a posterior compression of the state set (Felner et al. 2007), the construction itself works on a compressed data structure. Symbolic pattern databases are relations of pairs (f,x) , which are satisfied if the heuristic estimate of a states encoded in x matches the heuristic value encoded in f . Such relations can be represented as a BDD for the entire problem space or kept partitioned in form of breadth-first search layers $\text{Heur}[0], \dots, \text{Heur}[k]$. This list is initialized with the abstracted goal and, as long as there are newly encountered states, the set of predecessors with respect to the abstract transition relation is generated. For constructing symbolic

Figure 3.

shortest-path pattern databases, Dijkstra's algorithm can be adapted.

Symbolic Version of A*

Given a consistent heuristic h with $c(n, n') - h(n) + h(n') \geq 0$ for all states n and n' , A* (Hart et al. 1968) is in fact a variant of Dijkstra's algorithm using an initial offset $f(s) := h(s)$ and a refined update $f(n') := \min\{f(n'), f(n) + c(n, n') - h(n) + h(n')\}$.

BDDA* integrates symbolic and A* search (Edelkamp and Reffel 1998). It determines the successors of the set of states with minimum f -value in one evaluation step. Optimality and completeness of BDDA* are inherited from explicit-state A*. Starting from solving single-agent challenges BDDA* has been applied to hardware verification (Reffel and Edelkamp 1999) and planning problems (Edelkamp 2002). The efficiency has been reproduced by Hansen et al. (2002) and Qian and Nymeyer (2003).

To avoid finite domain arithmetics with BDDs, Jensen et al. (2002) has suggested a two-dimensional layout of state sets, one for each possible g - and h -value pair (see Figure 3). The advantage is that each state set already has the g - and the h -value attached to it, and the computation of the f -values for the set of successors are no longer needed. In the extension of BDDA* to weighted actions all successors of the set of states with minimum f -value, current cost g and action cost c can be determined individually.

For computing the image, constructing a monolithic relation Trans is not mandatory. Given that sub-relations $\text{Trans}[a]$ are linked to every action $a \in \{1, \dots, k\}$ the image of state set partitions into $\{\exists x (\text{Trans}[1](x, x') \wedge \text{States}(x))\} \vee \dots \vee \{\exists x (\text{Trans}[k](x, x') \wedge \text{States}(x))\}$.

FUTURE TRENDS

Symbolic search algorithms with BDD are also effective in solving non-deterministic search, and probabilistic search problems, see initial work by Cimatti et al. (1998) or Hoey et al. (1999). Recent trends include temporally extended goals as analyzed by Lago et al. (2002).

In order to save main memory, all but the currently expanded BDDs can be flushed to disk. As both explorations work on sets of states, a combination of disk-based search (to save RAM for the exploration) and symbolic pattern databases (to save RAM for the

estimate) turns out to be very effective. Distributed search may additionally save memory on the individual computing node. Successful explorations with up to 16 GB main memory and 3 TB disk space have been reported by Edelkamp and Jabbar (2007).

More advanced symbolic data structures can also cover infinite state sets. The exploration algorithms share similar algorithmic principles but have to be adapted. A recent proposal by Borowski and Edelkamp (2006) considers symbolic search in infinite-state systems with automata theory, where state sets and actions are represented as minimized finite state automata. The search repeatedly applies specialized image operators to compute the automata for the successor sets.

Another important future application area for symbolic search is the classification in general game play (Love et al. 2006), e.g. in the area of two-player games. First algorithms have been provided by Edelkamp and Kissmann (2007), which compute strategies in form of BDDs, assuming optimal play. Once computed, BDDs serve as finite-state controllers.

CONCLUSION

Symbolic search is an apparent option for the space-efficient traversal of state spaces bypassing the explicit memory-consuming representation of the state sets. The essentials of symbolic exploration in finite state systems with state sets that are represented as Boolean functions in form of BDDs have been presented, and various algorithms as well as their refined implementations including symbolic uni- and bidirectional breadth-first, single-source shortest paths, as well as heuristic search with pattern databases have been discussed.

KEY TERMS

Action Planning: Refers to a world description in logic, where a number of atomic propositions describe what can be true or false in each state of the world. By applying operators to a world, one arrives at another world, where different atoms might be true or false. Usually, only few atoms are affected by an action, and most of them remain the same.

Duplicate Elimination Scope: The number of layers that a back edge in a breath-first (or best-first) search graph can cross. It is an important parameter for the design of memory-limited frontier search algorithms and has application to improve the efficiency of both symbolic and disk-based search.

Model Checking: For a system model together with a formal description of a property, model checking is a push-button decision procedure. In case the desired property is not satisfied by the model, it returns a counter-example in form of a trace. Among the options for the specification of the model, there are Kripke structures and labelled transition systems. Valid choices for property specifications are linear and branching time logics, or the propositional μ -calculus.

Pattern Database: Given that state in a search problem is described as a vector of state variables, pattern variables denote a subset of them. They define an abstraction such that any path in the concrete state space induces a path in the abstract one. A pattern is a specific assignment of values to the pattern variables. A pattern database completely evaluates the abstract search space prior to the base level search in form of a lookup table indexed by the abstract containing the shortest goal distance.

Pattern Packing: Solves the pattern selection problem for constructing pattern database search heuristics. One bin represents a container for the abstract state space and approximates the memory usage for pattern database construction. Multiple bins apply for disjoint pattern database construction. In difference to standard bin packing, the effect of the selection of patterns is multiplicative.

Relational Product: Specialized procedure that combines conjunction and variable quantification in one specialized BDD operation.

Synthetic Neuron Implementations

Snorre Aunet

University of Oslo, Norway & Centers for Neural Inspired Nano Architectures, Norway

INTRODUCTION

Many different synthetic neuron implementations exist, that include a variety of traits associated with biological neurons and our understanding of them. An important motivation behind the studies, modelling and implementations of different synthetic neurons, is that nature has provided the most efficient ways of doing important types of computations, that we are trying to mimick.

Whether it is Artificial Neural Networks (ANNs) or other mixed signal systems, technology has always evolved in the direction of lower energy per unit computation (Mead, 1990). Simple Neuron models as threshold elements, or perceptrons, are promising candidates for implementing future signal processing systems, including CMOS and SET (Schmid & Leblebici, 2003), (Beiu & Ibrahim, 2007).

In this article a small number of published subthreshold, ultra low power, perceptrons / threshold elements are compared regarding power consumption, operational speed and defect tolerance. The “mirrored” gate operating in subthreshold and combined with redundancy, might be an interesting candidate for implementing artificial neural networks as well as other mixed-signal processing circuitry.

Previously unpublished results demonstrate the mirrored gate producing appropriate binary outputs at 180 mV supply voltage, even when a transistor was cut off the supply voltage, for a redundancy factor of 2, using shorted outputs, as in (Aunet & Hartmann, 2003).

BACKGROUND

CMOS has been the dominant technology for implementing signal processing systems for decades, and will probably live alongside other nanotechnologies for a long time (ITRS, 2005). Due to needs for low power operation for about any future signal processing technology and that CMOS and similar technologies probably will be mainstream for the foreseeable future,

the scope of this paper is limited to simple CMOS, ultra low power circuit topologies. Subthreshold circuits (Swansson & Meindl, 1972), using a supply voltage below the inherent threshold voltage of the transistors, consume less power than other low power circuits (Soeleman, Roy & Paul, 2001). Therefore we look at subthreshold neuron (“perceptron”) implementations in this paper, and concentrate on different metrics including circuit complexity, operational speed, power consumption and defect tolerance.

Reducing the power supply voltage through using ever more modern CMOS technologies and subthreshold operation reduces the number of inputs one could use for the threshold elements, depicted in Figure 1 (Aunet, 2002). Also, since only 2 inputs is optimal to implement any arbitrary neural network (Beiu & Markaruk, 1998) we have restricted the treatment to basic building blocks having a maximum fan-in of 3.

The first simple mathematical model of the biological neurons, published by McCulloch and Pitts in 1943, calculates the sign of the weighed sum of inputs. Sometimes such circuits are called threshold logic gates or threshold elements, illustrated in Figure 1. Such perceptrons may be used to implement Neural Networks as well as digital signal processing. For a review on a wide range of VLSI implementations the reader might confer (Beiu, Avedillo & Quintana, 2003).

Figure 1. The binary output, Y , depends on if the weighted sum of inputs X_1, X_2, \dots, X_n exceeds a certain Threshold, T .

ULTRA LOW POWER NEURONS, SPEED AND RELIABILITY

The main focus is on different subthreshold ultra low power perceptrons and how they compare regarding power consumption, operational speed and reliability.

MOS Transistors in Subthreshold

For an NMOS transistor in subthreshold we have (Andreou, Boahen, Pouliquen, Pavasovic, Jenkins & Strohhahn, 1991):

$$I_{ds,n} = I_0 e^{(\kappa V_{gs}/V_t)} e^{((1-\kappa)V_{bs}/V_t)} (1 - e^{(-V_{ds}/V_t)} + V_{ds}/V_0)$$

$I_{ds,n}$ expresses the current from drain to source. I_0 is the zero-bias current where the pre-exponential constants have been absorbed. This includes the channel width (“W”) and the length (“L”) of the MOSFET structure. V_{gs} is the gate-to-source potential, V_{ds} the drain-to-source potential and V_{bs} the substrate-to-source potential.

V_0 is the Early voltage, which is proportional to the channel length. κ gives the effectiveness for which the gate potential is controlling the channel current. It is often approximately 0.7-0.75 (Andreou, Boahen, Pouliquen, Pavasovic, Jenkins & Strohhahn, 1991). The thermal voltage is expressed as $V_t = kT/q$. $V_t = 25.8$ mV at room temperature.

A similar equation apply to PMOS transistors, but with opposite polarities. Exponential relationships

between voltages between several nodes and the current level mean that subthreshold circuits also have operational speed and power consumption that are extremely dependent on the supply voltage, V_{dd} . For example when operated at 10 kHz a subthreshold circuit used four orders of magnitude less than a regular strong inversion circuit implementing the same function (Soeleman, Roy & Paul, 2001).

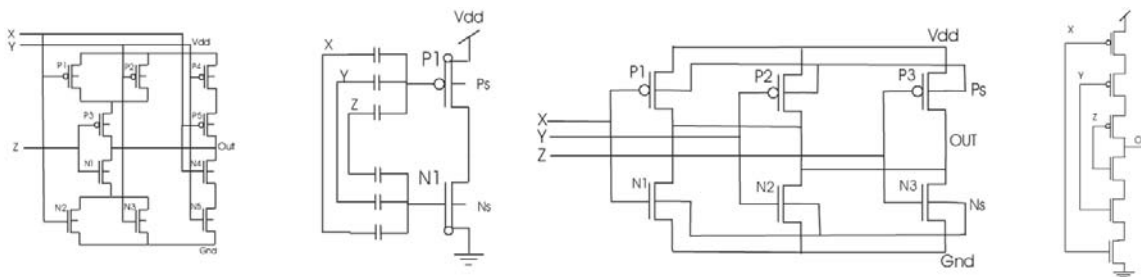

Low Fan-In Subthreshold Threshold Element (“Neuron”) Circuit Implementations

Recently published circuits are shown in Figure 2. The “mirrored gate” is a static CMOS solution (Beiu, Aunet, Nyathi, Rydberg III & Djupdal, 2005), based on (Hampel D., Prost K. J. & Scheinberg N. R., 1974). The floating-gate solution P3N3 (Aunet, 2002) might not go well along with future standard CMOS due to gate leakage, while the “ijcnn” (Aunet, Oelmann, Abdalla & Berg, 2004) and “stacked” (Aunet, Berg & Beiu, 2005) gates are CMOS.

Metrics Regarding Power Consumption and Maximum Operational Speed

Recently published results are shown in Figure 3 (Granhaug & Aunet, 2006). The “mirrored”, “ijcnn” and “stacked” gates were used for implementing 1-bit addition, Full Adders, in a 90 nm CMOS technology, and compared to a standard CMOS implementation (upper right corner in Figure 4).

Figure 2. Experimental setup for statistical simulation of 1-bit adder. From left to right they are called “mirrored”, “P3N3”, “IJCNN” and “Stacked” threshold elements.

In the upper left corner one can see that exploiting the “ijcnn” gate lead to the highest power consumption, while the “stacked” gate gave the lowest power consumption among the four implementations. Spice simulations were performed using a Cadence SW environment. The “mirrored” gate implementation resulted in a power consumption of 1160 pW, while the standard CMOS implementation had a slightly lower power consumption of 932 pW according to the simulations.

Regarding the maximum operational speed, shown upper right in Figure 3, the implementation based on the “stacked” gate (Figure 2.) could not compete, while the standard, “mirrored” and “ijcnn” gate implementations had delays of 162 ns, 159 ns and 174 ns, respectively. That the “mirrored” gate was slightly faster than the “ijcnn” gate is different to the findings in another publication (Aunet & Berg, 2005), where the “ijcnn” gate lead to a delay of 5.2 us, nearly twice as fast as the “mirrored” gate with it’s 9.15 us, implemented in a 120 nm CMOS technology and simulated operating at a supply voltage of 100 mV.

Manufacturability including Defect Tolerance

According to the ITRS Roadmap (ITRS, 2005), *reducing the overall power consumption and increas-*

ing the manufacturability are the two most important among five grand challenges for future nanoelectronics. Included in manufacturability are the possibilities to cope with a drastically increasing number of on-chip defects, as well as parameter variations. We have therefore included some data on the yield, meaning the expected percentage of circuits working under statistical variations in process parameters (Aunet & Otnes Berge, 2007).

A redundancy scheme for defect tolerance (Aunet & Hartmann, 2003) was used, exploiting shorted driven nodes and a redundancy factor of only 2 ($R = 2$), instead of redundancy factor 3 and a majority voter. Full Adders based on the three threshold elements depicted in Figure 2 were used, as well as the standard Full Adder (“FA”) in the upper right corner of Figure 4. A typical digital chip will fail if even a single transistor is defective (Mead, 1990). The results shown in the lower left corner of Figure 3 (Aunet & Otnes Berge, 2007) indicate that the solution based on $R = 2$ and the standard CMOS FA, as well as the solution based on the “mirrored” gate, should have a supply voltage above 150 mV if the implemented circuitry should expect a 100 % yield under the 90 nm CMOS production process variations.

When small size transistors were used here, for all four solutions, the “ijcnn” and “stacked” gates could not be expected to give a satisfying yield at supply voltages

Figure 3. Comparisons regarding power consumption, delay, tolerance to certain defects and complexity of circuitry when different threshold elements are used for 1-bit addition. A standard CMOS implementation is included for comparisons.

of 125 mV and 150 mV, since the gross majority of the circuits would not be expected to work.

Interconnect Challenges, and Neurons Leading to Simpler Circuitry

The number of defects in future nano technologies, including CMOS, will increase drastically. (Fortes, 2003), (ITRS, 2005). Defect tolerance must be part of about any system design (Lehtonen, Plosila & Isoaho, 2005). This include defects in interconnect and contacts. Few internal nodes generally reduce the amount of wiring and interconnect. From this viewpoint it might be preferable to have relatively few (driven) nodes as well as transistors. In this respect the “ijcnn” circuit is favorable among the four, as may be seen from figure 3 (Granhaug & Aunet, 2006).

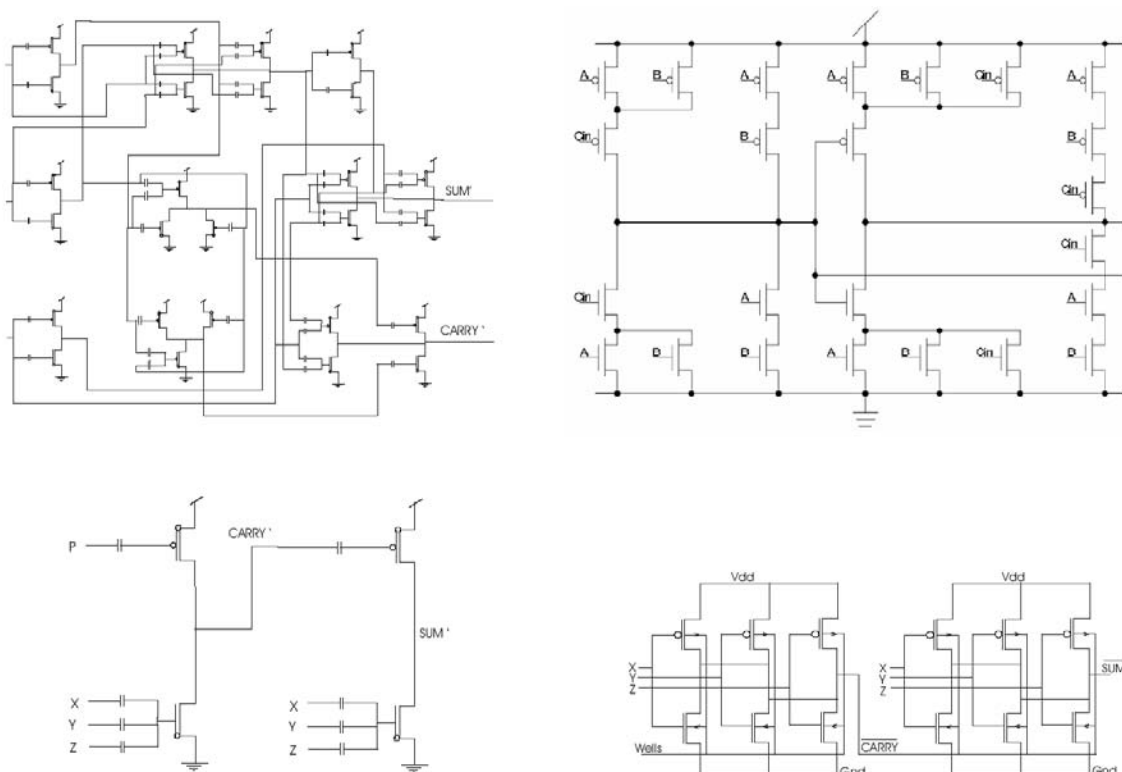

Boolean functions that can be realized by neurons are called linear threshold functions, and they can implement any Boolean function (Siu & Bruck, 1990). Using the linear threshold elements (perceptrons) for implementing such functions may save wires,

contacts and transistors, as the number of gates necessary to implement these important functions are growing linearly when using threshold elements, but exponentially if Boolean logic is used (Siu & Bruck, 1990). And: Regardless of the number of bits, Boolean gates will never lead to a lower number of gates than threshold elements.

This is also illustrated in figure 4, showing that the implementations (lower) depending on threshold elements / perceptrons are simpler and more regular than the traditional implementations, especially the floating-gate implementation based on pure Boolean logic, in the upper left corner.

As device and interconnect parameter variations imposes more problems in future nanoscale technologies it can also be of importance to have increasingly regular structures on chip to reduce for example dopant fluctuations that degrade performance due to transistor threshold voltage variations. In this respect perceptron implementations sometimes can be favorable, as illustrated in Figure 4, where the two lowermost schematics have a considerably higher regularity than

Figure 4. Four schematics showing circuits implementing SUM' and CARRY' for binary addition

the two others. This will reflect on the layout and the physical parameters.

“Mirrored” Gate in 90 nm CMOS Computing CARRY ‘ Function at $V_{dd} = 180$ mV

Figure 5 is showing measured results from an implementation of the “mirrored” gate computing the minority 3 function at 180 mV, both with and without a stuck-open fault, for a redundancy factor of $R = 2$. 16 binary input vectors $[X,Y,Z] = 000, 000, 001, 001, 010, 010, \dots, 111, 111$ were applied. The circuits computed the correct logic levels in all cases, producing a low output if, and only if, 2 or 3 out of three inputs were high. A low signal is less than 0.25 times the supply voltage of 180 mV, while a high signal should be at least 0.75 times the supply voltage.

This supply voltage is comparable to the low voltage of 175 mV published in (Miyazaki, Kao & Chandrakasan, 2002). Reducing the power supply voltage is the most direct and dramatic means of reducing the power consumption.

Discussion

Though the “stacked” gate had the lowest power consumption, it is the slowest. It does not have a low number of internal nodes and wires, which in addition to a relatively low yield according to the statistical Monte Carlo simulations might not make it the best candidate among the 4 implementations.

The “ijcnn” gate competes well regarding operational speed, but is the most power-hungry. On one hand it has the simplest topology, but the standard CMOS implementation as well as the “mirrored” gate show far better yields.

The “mirrored” gate implementation of the Full Adder competes well with the standard CMOS implementation overall (Granhaug & Aunet, 2006). These solutions might be interesting for further comparisons, as recent results have pointed out the “mirrored gate” as an interesting alternative, exemplified by the following title; *Why Inverters and Small Fan-In Voters are The Most Promising Gates for Future Nanoelectronics* (Beiu & Ibrahim, 2007).

Figure 5 . Measured results

FUTURE TRENDS

The assumption that a system is composed largely of correctly functioning units is no longer true in emerging nanoelectronics, and reducing the overall power consumption is also among the grand challenges for the future. The low fan-in perceptrons, also called *voters*, or *minority gates*, might be very useful candidates for future nanoelectronics, which has been recently stated (Beiu & Ibrahim, 2007), and is not in disagreement with results presented here. Defect tolerant subthreshold perceptron circuits exploiting majority gates, as presented here, may thus become very useful.

Perceptrons may also prove to be useful building blocks for other future nanotechnologies, including SET (Beiu, Avedillo & Quintana, 2003).

CONCLUSION

We have argued that future needs for low power consumption and defect tolerance make subthreshold neuron implementations useful for artificial neural network. From the results and discussion presented here we conclude that the “mirrored” gate may be particularly useful in the mentioned respects. It may be combined with redundancy for defect tolerance and increased manufacturability, which could be useful for future nanotechnologies.

The ability of the “mirrored” gate to function under the presence of defects, when exploiting redundancy, was demonstrated by chip measurements for a 90 nm CMOS technology.

KEY TERMS

Full Adder: Circuit that produces the binary sum and carry when adding two binary numbers.

Mismatch: Ideally identically constructed elements on an integrated circuits have a mismatch when they differ in their physical properties after production of the chip.

Minority-3 Gate: A minority 3 gate outputs a logic “0” signal if, and only if, 2 or 3 out of its three binary inputs are “1”.

Monte Carlo Simulations: Computer simulations basing the results on statistical distribution of parameters.

Nanoscale CMOS: CMOS technologies where dimensions smaller than 100 nm is critical to the functioning of the produced chip.

Neuron: Electrically excitable cells in the nervous system that process and transmit information.

Parameter Variations: Parameters describing physical traits of integrated circuits may have variations due to mismatch, for example the threshold voltages of transistors.

Perceptron: Type of artificial (feedforward) Neural Network.

SET: Single Electron Transistor.

Yield: In this paper the term yield refers to the ratio of functional circuits to the total number of simulated circuits. Often yield refers to the ratio of functional chips to the total number of manufactured chips.

Teaching Machines to Find Names

Raymond Chiong

Swinburne University of Technology, Sarawak Campus, Malaysia

INTRODUCTION

In the field of Natural Language Processing, one of the very important research areas of Information Extraction (IE) comes in Named Entity Recognition (NER). NER is a subtask of IE that seeks to identify and classify the predefined categories of named entities in text documents. Considerable amount of work has been done on NER in recent years due to the increasing demand of automated texts and the wide availability of electronic corpora. While it is relatively easy and natural for a human reader to read and understand the context of a given article, getting a machine to understand and differentiate between words is a big challenge. For instance, the word 'brown' may refer to a person called Mr. Brown, or the colour of an item which is brown. Human readers can easily discern the meaning of the word by looking at the context of that particular sentence, but it would be almost impossible for a computer to interpret it without any additional information.

To deal with the issue, researchers in NER field have proposed various rule-based systems (Wakao, Gaizauskas & Wilks, 1996; Krupka & Hausman, 1998; Maynard, Tablan, Ursu, Cunningham & Wilks, 2001). These systems are able to achieve high accuracy in recognition with the help of some lists of known named entities called gazetteers. The problem with rule-based approach is that it lacks the robustness and portability. It incurs steep maintenance cost especially when new rules need to be introduced for some new information or new domains.

A better option is thus to use machine learning approach that is trainable and adaptable. Three well-known machine learning approaches that have been used extensively in NER are Hidden Markov Model (HMM), Maximum Entropy Model (MEM) and Decision Tree. Many of the existing machine learning-based NER systems (Bikel, Schwartz & Weischedel, 1999; Zhou & Su, 2002; Borthwick, Sterling, Agichten & Grisham, 1998; Bender, Och & Ney, 2003; Chieu & Ng, 2002; Sekine, Grisham & Shinnou, 1998) are able to achieve near-human performance for named entity

tagging, even though the overall performance is still about 2% short from the rule-based systems.

There have also been many attempts to improve the performance of NER using a hybrid approach with the combination of handcrafted rules and statistical models (Mikheev, Moens & Grover, 1999; Srihari & Li, 2000; Seon, Ko, Kim & Seo, 2001). These systems can achieve relatively good performance in the targeted domains owing to the comprehensive handcrafted rules. Nevertheless, the portability problem still remains unsolved when it comes to dealing with NER in various domains.

As such, this article presents a hybrid machine learning approach using MEM and HMM successively. The reason for using two statistical models in succession instead of one is due to the distinctive nature of the two models. HMM is able to achieve better performance than any other statistical models, and is generally regarded as the most successful one in machine learning approach. However, it suffers from sparseness problem, which means considerable amount of data is needed for it to achieve acceptable performance. On the other hand, MEM is able to maintain reasonable performance even when there is little data available for training purpose. The idea is therefore to walkthrough the testing corpus using MEM first in order to generate a temporary tagging result, while this procedure can be simultaneously used as a training process for HMM. During the second walkthrough, the corpus uses HMM for the final tagging. In this process, the temporary tagging result generated by MEM will be used as a reference for subsequent error checking and correction. In the case when there is little training data available, the final result can still be reliable based on the contribution of the initial MEM tagging result.

BACKGROUND

Message Understanding Conference

In 1987, the Naval Ocean Systems Center (NOSC), which is presently known as the Naval Command,

Control and Ocean Surveillance Center, initiated the first Message Understanding Conference (MUC). Subsequently, a series of MUCs had been held and designed to promote and evaluate research in IE. The evaluations achieved through these MUCs have led the research program in IE until its present state.

In 1995, goals and tasks were set up for MUC-6 to make the IE system more practical with an aim to achieve automatic performance with high accuracy. “Named Entity” was then developed to help identifying the names of persons, organizations, and geographic locations in a text. Since then, the NER tasks have become a central theme in MUC (see Chinchor, 1995 and Chinchor, 1998 for more details).

According to the specifications defined by MUC, the NER tasks generally work on seven types of named entities as listed below with their respective markup:

- PERSON (ENAMEX)
- ORGANIZATION (ENAMEX)
- LOCATION (ENAMEX)
- DATE (TIMEX)
- TIME (TIMEX)
- MONEY (NUMEX)
- PERCENT (NUMEX)

From the list above, three subtasks are derived from these seven types of named entities and assigned with three respective SGML tag elements, namely ENAMEX, TIMEX and NUMEX. As TIMEX and NUMEX are fairly easy to predict with some effective finite state methods (Roche & Schabes, 1997), most of the current research deals only with ENAMEX which are highly variable and ambiguous.

Previous Approaches

Since MUC-6 and MUC-7, many NER systems have been proposed and proven to be successful in their targeted domains. In general, NER systems that use handcrafted rules still lead the way, with the highest F-measure score up to 96.4% achieved in MUC-6 as compared to the statistical approaches that were able to achieve 94.9% (Zhou & Su, 2002).

In rule-based approach, a set of rules or patterns is defined to identify the named entities in a text. These rules or patterns consist of distinctive word format, such as capitalization or particular preposition prior to a named entity. For instance, a capitalized string

behind titles such as ‘Mr’, ‘Dr’, etc will be identified as name of a person, whereas a capitalized word after a preposition such as ‘in’, ‘at’, ‘near’, etc is most likely to be a location. By implementing a finite set of carefully predefined pattern matching rules, the named entities within a text could be found systematically.

There have been substantial amount of works done using the rule-based approach. One of the very well documented systems that followed the direction of this approach was the framework of the LaSIE System reported by Wakao et al. (1996). Another well-known example of rule-based system can be found in the IsoQuest’s NetOwl Text Extraction System presented by Krupka and Hausman (1998). Meanwhile, Diana Maynard et al. (2001) had also built an NER system based on handcrafted rules that is able to achieve an average of 93% precision and 95% recall across diverse text types.

Statistical approach, on the other hand, works by using a probabilistic model containing features to the data which are similar to the rule-based approach. The features of the data, which could be understood as rules set for the probabilistic model, are produced by learning the resulting corpora with correctly marked named entities. The probabilistic model then uses the features to calculate and identify the most probable named entities. As such, if the annotated features of the data are truly reliable, the model would have a high probability in finding almost all the named entities within a text.

In the last decade, large amount of works in NER have been done using the statistical approach based on some very large corpora. The MEM, one of the most popular statistical models, has been applied frequently in various NER tasks. One significant account on MEM is the MENE system reported by Borthwick et al. (1998). In their system, they used four main features to identify the named entities, which they referred to as the binary features, lexical features, section features and dictionary features.

The binary features in MENE system basically deal with capitalization in the text. Meanwhile, lexical features are concerned with the lexical terms such as list of words and their types which are used with a grammar. Section features indicate a current section of the text, whereas the dictionary features make use of a broad array of dictionaries of single or multiple terms such as first names, organization names, corporate suffixes, etc. The dictionary features are similar to the gazetteers

used for rule-based systems, except that dictionaries in MENE system require no huge maintenance effort.

Nevertheless, using MENE system alone on the MUC-7 test data as reported in Borthwick et al. (1998) achieved only an F-measure of 84.22%. For MENE system to work better, Borthwick et al. combined MENE with other rule-based approaches in order to achieve superior results.

Besides Borthwick et al., Bender et al. (2003) also reported on an NER system that was able to achieve an F-measure score of 89.58% by using MEM. With an annotated corpus and a set of features, they first built a baseline named entity recognizer which was then used to extract the named entities and their contextual information from non-annotated data. The accuracy of their system was further improved with a final recognizer that made use of the trained data.

Another MEM-based system can be found in Chieu and Ng (2002). They presented a system called MEN-ERGI that made use of global information with just one classifier, and showed that their system was able to achieve performance comparable to the best machine learning-based systems in MUC-6 and MUC-7.

Apart from MEM, HMM is another well-known statistical model that has been used frequently in various NER systems. The IdentiFinder reported by Bikel et al. (1999) using a modified HMM was the best-performer on the official MUC-6 and MUC-7 test data among all the machine learning-based systems. IdentiFinder employed similar features to those of MENE system, and depended on statistics to make decision in identifying the named entities. It is different in a way that it has a complete probabilistic model that governs all decisions in classifying the named entities and models the categories of interest and the residual input that is not of interest.

The modified HMM used by IdentiFinder was subsequently adopted by Zhou and Su (2002). In their work, they were able to increase the performance of their NER system dramatically by introducing four sub-features with back-off modelling. Using the test data from MUC-6 and MUC-7, their system was able to achieve F-measure scores of 96.6% and 94.1% respectively.

Many more previous works were done using statistical models other than MEM and HMM. There are also many NER systems that use a hybrid approach by combining the statistical models with some rule-based learning techniques. One very successful example can

be found in the work of Mikheev et al. (1999), where they used substantial handcrafted rules together with MEM for partial matching. Observation on the previous approaches, however, shows that no system has ever tried to use MEM and HMM successively.

THE HYBRID APPROACH

As mentioned before, the NER system presented in this article uses two statistical models – MEM and HMM – in succession. The MEM is based on the MENE system reported by Borthwick et al. (1998) whereas the HMM is based on the IdentiFinder reported by Bikel et al. (1999). The system is built with Java using the existing implementation from the JavaNLP repository which is available at <http://nlp.stanford.edu/javanlp/>. For training and experimental purposes, British National Corpus (BNC) which contains texts that are diverse in terms of domain, style and genre has been chosen to be the testing corpus. This is to ensure that the proposed NER system is domain-independent and can adequately cope with a variety of text types.

Maximum Entropy

By following the guidelines from MUC-6 and MUC-7 for the definition of the NER task, every word from the corpus is tokenized and assigned to a desired category of named entity with the tag of either “person” (<PER>), “organisation” (<ORG>) or “location” (<LOC>). MEM is first used to estimate the probability of a given word being fallen into one of the three categories mentioned based on a set of features and some training data. Two special conditions are taken into consideration when a word falls at the beginning (<START>) and at the end (<END>) of a sentence. In the case when a given word does not fall into any of the desired categories, empty tag (<>) will be placed to indicate that the word belongs to none of the desired categories.

For the purpose of finding named entities, the maximum entropy estimation process uses a model that is described below to compute the conditional probability P for all tags t based on the history h , in which every feature f_i is associated with it a weighting parameter α_i :

$$\sup_{\theta \in \Omega} \sup_{x, y \in \Omega} \frac{p_{\theta}(y)}{q(x, y)} < \infty$$

It is necessary to note that the history h mentioned in the model refers to all the conditioning data that enable the system to make a decision on the tagging process. It comprises of all information derivable from the corpus relative to a token whose tag the system is trying to determine, may it be the word itself or the features. The product of the weightings for all features active on h will then be calculated, and eventually be divided by a normalization function, $Z_a(h)$.

Hidden Markov Model

After the MEM walkthrough, all the tagged named entities in the testing corpus are used as training data for HMM to make the final tagging. Since there will be sufficient training after parsing through the corpus using MEM, it is not necessary for the system to use the back-off models such as those used by Bikel et al. (1999) and Zhou and Su (2002).

In this system, HMM is used mainly for global context checking, that is to check the occurrences of the same named entity in different sections of the same text document. Checking the context from the whole document is important as this will ensure the consistency of the tagged named entities and resolve some ambiguous cases. For instance, an organization's name is often abbreviated especially when it has already been mentioned somewhere in a document. By checking the global information, the abbreviation as an organization can be identified. Besides that, there are also some entities that are highly ambiguous, and their categories cannot be determined without taking the global context into consideration. The phrase 'Honda City' in sentences such as "Honda City is nice" or "Promotion for Honda City" could easily be misinterpreted as a location based on the local contextual evidence, unless there is another sentence that sounds like "I am driving Honda City".

Similar to the previously used MEM, HMM is used to compute the likelihood of words occurring within a given category of named entity. Every tokenized word is now considered to be in ordered pairs. By using a Markov chain, the likelihood of the words is calculated simply based on the previous word.

For classifying the named entities, the system finds the most likely tag t for a given sequence of words w that maximizes $P(t|w)$. The occurrences of the given events are counted throughout the whole text based on

the calculation below:

$$P(t | t_{-1}, w_{-1}) = \frac{\text{count}(t, t_{-1}, w_{-1})}{\text{count}(t_{-1}, w_{-1})}$$

Finally, a classifier is used to correct the errors in the results derived from MEM to perform the final tagging process using HMM.

Experimental Results

The proposed system has been tested with articles from BNC based on a wide range of domains from different fields. With the successive use of MEM and HMM, it is able to maintain a desirable performance regardless of the size of training data. In overall, the system achieved F-measure scores above 95% consistently for most of the commonly used domains. A detailed description of the system and its experimental results can be found in Chiong and Wang (2006).

FUTURE TRENDS

While the preliminary results on the hybrid approach have been quite positive, the proposed system is still fairly immature. Much work needs to be done to make the performance of the system more robust. For instance, it will be interesting to see how more sophisticated features can be incorporated to improve the performance of the system. It will also be interesting to see how the system can be trained on corpora in foreign languages.

In the future, it is anticipated that the proposed approach can be valuable in various Natural Language applications. One immediate contribution can be seen in automating the arduous task of ontology building. Meanwhile, Automatic Text Summarization Systems can also be enriched by the proposed system, as named entities are able to provide clues for identifying relevant segments in text. Last but not least, the proposed approach is expected to help in building more accurate Internet search engines too.

CONCLUSION

This article presented a hybrid machine learning approach that used MEM and HMM successively. With the preliminary data training through MEM and appropriate classifier for error correction in the final recognition process through HMM, the performance of the proposed NER system can be greatly enhanced as compared to using only a single statistical model. Moreover, the system is also able to adapt to different domains without human intervention, and maintained desirable performance regardless of the size of the training corpus.

KEY TERMS

British National Corpus (BNC): A 100 million word collection of samples of written and spoken language from a wide range of sources, designed to represent a wide cross-section of current British English, both spoken and written.

Gazetteer: A list of named entities with the names of persons, organizations, locations, expressions of times, quantities, monetary values, percentages, etc.

Hidden Markov Model (HMM): A statistical model for determining the hidden parameters based on the observable parameters using probability distribution in order to perform analysis and pattern recognition.

Information Extraction (IE): A process of selecting information from a dataset or text based on certain specifications using templates, and it is often delivered in the form of fragments of documents.

Machine Learning: An area of study concerning the development of techniques which allow machines or computers to improve their performance based on previous results and learning experience.

Maximum Entropy Model (MEM): A statistical model for analyzing the available information in order to determine a unique epistemic probability distribution based on partial information about the probabilities of possible outcomes of an experiment, and chooses the probabilities so as to maximize the uncertainty about the missing information.

Named Entity Recognition (NER): A subtask of IE that seeks to identify and classify named entities in text into predefined categories such as the names of persons, organizations, locations, expressions of times, quantities, monetary values, percentages, etc.

Natural Language Processing (NLP): An area of study concerning the problems inherent in the processing and manipulation of natural language with the aim to make computers understand statements written in human languages.

The Hong Kong Polytechnic University, Hong Kong

INTRODUCTION

Recent advances in the applications of ANN have demonstrated successful cases in time series analysis, data mining, civil engineering, financial analysis, music creation, fishing prediction, production scheduling, intruder detection, etc., making them an important tool for research and development[1]. ANN and evolutionary computation(EC) techniques have been employed successfully in solving real-world problems including those with a temporal component[2]. In another work[3], a hybrid method based on a combination of evolutionary computation and neural network(NN) has been used to predict time series.

In the world of databases, various ANN-based strategies have been used for knowledge search and extraction[4]. Intelligent neural systems have been constructed with the aid of genetic algorithm-based EC techniques and these systems have been applied in breast cancer diagnosis[5]. Genetic algorithms(GA) have been applied to develop a general method of selecting the most relevant subset of variables in the field of analytical chemistry to classify apple beverages[6]. New ANN methods enable civil engineers to use computing in different ways. Besides as a tool in urban storm drainage[7], ANN and Genetic Programming(GP) have been implemented in the prediction and modelling of the flow of a typical urban basin [8]. In the latter case, it was shown that these two techniques could be combined in order to design a real-time alarm system for floods or subsidence warning in various types of urban basins. ANN models for consistency, measured by slump, in the case of conventional concrete have also been developed[9]. In a time series prediction of the quarterly values of the medical component of the Consumer Price Index(CPI), the results obtained with both neural and functional networks have been shown

to be quite similar[10]. Dimensionality reduction, variable reduction, hybrid networks, normal fuzzy and ANN have been applied to predict bond rating[11].

A recent online survey through the ISI Web of Knowledge using keywords such as “ANN” and “thermal design” would reveal only ten relevant SCI publications[12]. In the area of food processing, ANN was used to predict the maximum or minimum temperature reached in the sample after pressurization and the time needed for thermal re-equilibration[13]. The accurate determination of thermophysical properties of milk is very important for design, simulation, optimization, and control of food processing such as evaporation, heat exchanging, spray drying, and so forth. Generally, polynomial methods are used for prediction of these properties based on empirical correlation to experimental data. However, it was found that ANN presented a better prediction capability of specific heat, thermal conductivity, and density of milk than polynomial modeling and it was suggested as a reasonable alternative to empirical modeling for thermophysical properties of foods[14].

Numerical simulation of natural circulation boiling water reactor is important in order to study its performance for different designs and under various off-design conditions. It was found that very fast numerical simulations, useful for extensive parametric studies and for solving design optimization problems, can be achieved by using an ANN model of the system[15]. ANN models and GA were applied for developing prediction models and for optimization of constant temperature retort thermal processing of conduction heating foods[16]. ANN technique has been used as a new approach to determine the exergy losses of an ejector-absorption heat transformer (EAHT)[17]. The results show that the ANN approach has the advantages of computational speed, low cost for feasibility, rapid

turnaround, which is especially important during iterative design phases, and easy of design by operators with little technical experience.

Computational fluid dynamics approach is often employed for heat transfer analysis of a ball grid array (BGA) package that is widely used in the modern electronics industry. Owing to the complicated geometric configuration of the BGA package, an ANN was trained to establish the relationship between the geometry input and the thermal resistance output [18]. The results of this study provide the electronic packaging industry with a reliable and rapid method for heat dissipation design of BGA packages. Thermal spraying is a versatile technique of coating manufacturing implementing large variety of materials and processes. An ANN was developed to relate processing parameters to properties of alumina-titania ceramic coatings [19]. Predicted results show globally a well agreement with the experimental values.

It can be seen that applications of ANN in thermal design is scarce and this article aims to explore the application of an ANN in gas-fired cooktop burner design.

BACKGROUND

Cooktop Design Goals

Gases that trap heat in the atmosphere are often called greenhouse gases. They include carbon dioxide, nitrous oxide, methane, and ozone. Individuals can produce greenhouse gas emissions directly by burning oil or gas for home heating and cooking or indirectly by using electricity generated from fossil fuel burning. In the last 200 years, mankind has been releasing substantial quantities of greenhouse gases into the atmosphere. These extra emissions are increasing greenhouse gas (GHG) concentrations in the atmosphere, enhancing the natural greenhouse effect, which is believed to be causing global warming.

To combat the global warming problem, gas suppliers and manufacturers of cooking appliances are trying to find ways of improving energy efficiency with reducing greenhouse gas emissions. In view of the number of controllable factors and responses to be studied, Design of Experiments (DOE) is often used for such kind of empirical investigations. The authors therefore proposed to combine DOE technique with

the ANN approach for solving the multiple input and multiple output (MIMO) design problem. To achieve optimal thermal efficiency and greenhouse gas emissions, a back-propagation ANN was used to simulate the operating conditions and the implementation details are illustrated through a real-life case.

EMPIRICAL STUDY

A three factor, three level, Full Factorial Design (with 3 repetitions) was employed to investigate the complex relationships of three design parameters of a cooktop burner, viz. the Reynolds number, the equivalence ratio, and the load-height (distance from nozzle to bottom surface of cookware). The range of Reynolds number (Re) considered varies from 400 to 700. A tailor-made cooktop burner with a ring of 128 mm diameter is used and circular nozzles (diameter = 6 mm) were used in the experiment. Fuel-rich flames (corresponding to equivalence ratios ranging from 1.4 to 1.8) similar to real-life cooking situations were employed in the experiments. The load-height ranges from 24 mm to 32 mm (corresponding to a H/d ratio varying from 4 to 8). To allow for different spacing between groups of nozzles, four configurations of the cooktop burner were considered, viz. 2-nozzle 6-section, 3-nozzle 4-section, 4-nozzle 3-section and 6-nozzle 2-section configurations. These nozzle configurations were labeled 1, 2, 3 and 4 respectively (Fig. 2). A total of 108 experiments were carried out for each configuration. Experiment results showed that the configuration of 3-nozzle 4 section based on the predetermined input conditions of Re=550, EqR=1.6 and H/d=8 would give the best thermal efficiency (62%) and acceptable CO and NO_x emissions,

- Burner efficiency model

The thermal efficiency of a burner is defined as the percentage of the thermal input transferred to the water in the loading vessel. It was determined by measuring the elapsed time for a standard 4 kg load of water to be heated from 30°C to 80°C and the corresponding consumption of LPG. Mathematically, the thermal efficiency is calculated as:

$$\eta = (MC_p \Delta T / Q_{H_v}) * 100\% \quad (1)$$

where, $M(\text{kg})$ is the load mass of water, $C_p(\text{kJ/kg}^\circ\text{C})$ is the specific heat of water, $Q(\text{m}^3)$ is the LPG consumption, $\Delta T(^\circ\text{C})$ is the temperature rise and $H_v(\text{kJ/m}^3)$ denotes the heating value of LPG.. An analysis of variance (ANOVA) on the data collected indicated that the quadratic regression model shown in Eqn.(2) could adequately describe the thermal efficiency (η). Stepwise method was used to remove the insignificant terms.

$$\eta = 0.49 - 0.05A - 0.038B + 0.17C - 0.039CD + 0.021B^2 - 0.18C^2 \quad (2)$$

Where, $-1 \leq A, B, C \leq 1$ corresponding to

$$400 \leq \text{Re} \leq 700; 1.4 \leq \text{Re} \leq 1.8; 4 \leq H/d \leq 8$$

The adjusted multiple correlation and the adequate precision coefficients were found to be 0.95 and 29.63 respectively.

- Burner emission models

Similarly, based on the values of Adjusted Multiple Correlation and Adequate Precision coefficients generated from the ANOVA results, the regression models shown in Eqn.(3) and Eqn.(4) adequately describe the CO and NOx emissions.

$$\text{CO} = 1790.22 + 745.27A + 557.01B - 1721.41C + 280.57AB - 251.97AC - 39.19BC + 31.54A^2 - 67.06B^2 + 481.87C^2 \quad (3)$$

$$\text{NOx} = 51.10 - 6.99A - 6.26B + 23.90C + 2.22AB - 3.77AC - 5.58BC \quad (4)$$

It is noted from the efficiency and emission models that the combined effects of some design factors can have considerable impact on the responses.

ANN OPTIMIZATION OF COOKTOP DESIGN

For this MIMO system, the architecture of the neural network can have several layers. Each layer has a weight matrix **W**, a bias vector **b**, and output vector **a**. Generally, a network of two layers, where the first layer is sigmoid and the second layer is linear, can be employed to approximate any function reasonably well

and such structure was adopted in this case. The two layers of neurons with nonlinear transfer functions allow the network to learn nonlinear and linear relationships between input and output vectors.

The output of i^{th} neuron in the hidden layer is:

$$a1_i = f_1(\sum w1_{ij}p_j + b1_i), i = 1, 2; j = 1, 2$$

For the output of k^{th} neuron in the output layer is:

$$a2_k = f_2(\sum w2_{kj}a1_i + b2_k), k = 1, 2; j = 1, 2$$

The error function is defined as:

$$E(W, B) = (1/2)\sum(t_k - a2_k)^2$$

Gradient Method was used for calculation of weight variation and the back-propagation of the error, when training the network.

Weight Variation of the output model is:

$$\Delta w2_{kj} = -\eta(\delta E / \delta w2_{kj}) = -\eta(\delta E / \delta a2_k)(\delta a2_k / \delta w2_{kj})$$

$$\Delta b2_{kj} = -\eta(\delta E / \delta b2_{kj}) = -\eta(\delta E / \delta a2_k)(\delta a2_k / \delta b2_{kj})$$

Weight variation of the hidden layer is:

$$\Delta w1_{kj} = -\eta(\delta E / \delta w1_{kj}) = -\eta(\delta E / \delta a2_k)(\delta a2_k / \delta w2_{kj})(\delta a1_i / \delta w1_{ij})$$

$$\Delta b1_i = \eta \delta_{ij}$$

Before training, it is necessary to scale the inputs and targets so that they always fall within a specified range. In the neural network model above, it is found that if preprocess and postprocess procedures are omitted, the network can hardly achieve the designed goal. This is due to large magnitude differences between the input and output parameters, e.g.: efficiency is in the range of 0.4 to 0.68, but CO emission(in ppm) is in the range of hundreds. All the input and output data was so scaled that they would fall within the range of $[-1, 1]$. The initialization of the weights and bias for each layer is important before training a feed-forward network. If improper values were chosen, training time would be excessive and the network could not convergent. As the characteristics of the actual operating condition are unknown, random initialization is used.

Figure 1. MSE trend

For each cooktop burner configuration, 90 sets of experiment results were used to train the neural network, and the remaining 18 were used to evaluate whether the network can represent the model of cooktop well. Mean square error(MSE) was used to test the performance of the network. It was found that the neural network performed reasonably well for the testing data. 32 neurons were used in the hidden layer, and for an average training time of 200~300 epochs, MSE could easily dropped to 10^{-5} (Fig. 1).

As the NN model performed quite well after training by using the actual experimental data, it is used to simulate the real environment of the experiments. After a simulation of all the reasonable combinations of the three initial factors, a maximum value of the thermal efficiency (corresponding to low CO and NO_x emissions) was found.

There were four nozzle configurations in the simulation, the same as in the experiment. For each nozzle configuration, the number of simulations was:

$$[(700-400)/5]*[(1.8-1.4)/0.05]*[(8-4)/1] = 1,920$$

After the simulation, the first step was to choose the results that could meet the Chinese National Standard on Gas Appliances: thermal efficiency $\geq 60\%$, CO emission ≤ 300 (ppm), NO_x emission ≤ 100 (ppm). The second step was to find the maximum value of the thermal efficiency, from this value the corresponding combination of input factors and configuration type of

cooktop were found. The simulation results showed that while the 2-nozzle and 3-nozzle configurations satisfied the National Standards, the 3-nozzle configuration indicates slightly better results: the thermal efficiency reaches 62.8% and the CO and NO_x emissions are 257 and 91 respectively. Fig. 2 shows a comparison of thermal efficiency, CO and NO_x emissions for each nozzle configuration respectively.

To confirm the validity of the NN results, three additional experiments based on the optimum values were carried out. Table 1 shows a comparison of the predicted and observed responses for the 3-nozzle burner configuration under optimal conditions. It can be seen that the predicted values of efficiency and NO_x emission are close to the experimental values. The difference between the predicted and the observed values are about 15%.

FUTURE TRENDS

Through this study one can see that artificial neural networks, as in other real-life applications, offer cooktop designers a highly versatile new tool for the thermal design of gas-fired cooktop burners. The successful utilization of this procedure requires that the ANN be fully optimized. In this study, backpropagation, a local search algorithm, was used for optimization and it is likely that local optimum rather than the global was obtained. One may attempt to address this problem

Figure 2. Comparison of ANN simulation results

with *ad hoc* procedures such as stopping optimization at sub-optimal solutions(not over-training) or adjusting the neural network architecture to make optimization easier. As shown in other engineering applications[1], a promising alternative would be the use of a global optimization algorithm such as the genetic algorithm.

It is anticipated that by using a global search algorithm, the objective function can be set to balance the tradeoff between the over parameterization of the model that may over fit the data and a parsimonious ANN that can provide a more robust solution.

Table 1. A comparison of NN prediction and experimental results at optimal design

| Re | EqR | H/d | Responses | | | | | |
|-----|------|-----|------------|----------|----------------------------|----------|---|----------|
| | | | Efficiency | | CO (ppm@0%O ₂) | | NO _x (ppm@0%O ₂) | |
| | | | Predicted | Observed | Predicted | Observed | Predicted | Observed |
| 580 | 1.65 | 8 | 0.63 | 0.60 | 257 | 292 | 91 | 98 |

CONCLUSION

A problem facing the gas-fired cooktop burner design community is the determination of design parameters which will result in a product with the most desirable combination of functional outcomes. Through an empirical investigation on the simultaneous optimization of thermal efficiency and GHG emissions, ANN methodology has proved to be an effective empirical modeling tool. Both the multiple correlation (R^2) and the mean square error (MSE) of ANN models for efficiency, CO and NO_x emissions indicated that the ANN results were quite satisfactory. Through multiple regression modeling one can evaluate the significance of the main and combined effects of various design parameters on burner efficiency and emissions. The relationship between the gas-fired burner design parameters and performance is hence further understood. To enhance the optimizing capabilities of the proposed ANN, a global search algorithm such as GA should be used instead of the backpropagation algorithm. It is believed that a GA-based ANN would provide a practical tool for the mechanical engineering design community.

KEY TERMS

Backpropagation: A supervised learning technique used for training artificial neural networks. It is most useful for feed-forward networks (networks that have no feedback, or simply, that have no connections that loop). The term is an abbreviation for “backwards propagation of errors”. Backpropagation requires that the transfer function used by the artificial neurons (or “nodes”) be differentiable.

Full Factorial Design: This design allows a designer to adequately quantify a response with a reasonable number of tests. In general, full factorial designs require three levels for each factor thus allowing one to evaluate second order models.

Designed of Experiments: A set of tests conducted under controlled conditions in which multiple levels of a set of factors are manipulated and the resulting response(s) of a system or process is measured or observed.

Factors: The set of (independent) variables that are believed to affect the response of a system or process.

Levels: The sets of values for each factor.

Multilayer Perceptrons (MLPs): They are feed-forward neural networks trained with the standard backpropagation algorithm. They are supervised networks so they require a desired response to be trained. They learn how to transform input data into a desired response, so they are widely used for pattern classification. With one or two hidden layers, they can approximate virtually any input-output map.

Multiple Correlation, R²: the percent of variance in the dependent variable explained collectively by all of the independent variables.

Response: The (dependent) variable(s) measured or observed that is the result of a test conducted at a specific set of factor levels.

Reynolds Number(Re): the ratio of inertial forces to viscous forces and consequently it quantifies the relative importance of these two types of forces for given flow conditions. Thus, it is used to identify different flow regimes, such as laminar or turbulent flow.

A 2D Positioning Application in PET Using ANNs

INTRODUCTION

Positron Emission Tomography (PET) is a radiotracer imaging technique based on the administration (typically by injection) of compounds labelled with positron emitting radionuclides to a patient under study. When the radio-isotope decays, it emits a positron, which travels a short distance before annihilating with an electron. This annihilation produces two high-energy (511 keV) gamma photons propagating in nearly opposite directions, along an imaginary line called Line of Response (LOR).

In PET imaging, the photons emitted by the decaying isotope are detected with gamma cameras. These cameras consist of a lead collimator to ensure that all detected photons are propagated along parallel paths, a crystal scintillator to convert high-energy photons to visible light, photo-multiplier tubes (PMT) to transform light signals into electric signals, and associated electronics to determine the position of each incident photon from the light distribution in the crystal (Ollinger & Fessler, 1997).

We have researched on how Artificial Neural Networks (henceforth ANNs or NNs) could be used for bias-corrected position estimation. Small-scale ANNs like the ones considered in this work can be easily implemented in hardware, due to their highly parallelizable structure. Therefore, we have tried to take advantage of the capabilities of ANNs for modelling the real detector response.

BACKGROUND

Traditionally, Anger logic (Anger, 1958) has been the most popular technique to obtain the the position of the *centroid*, or centre of the light distribution inside the scintillator crystal by means of a simple formula. The solution proposed by Anger involves connecting the PMT outputs to a simple resistor division circuit to obtain only four signals (X^- , X^+ , Y^- , Y^+). However, Anger logic introduces some important drawbacks in the detection process: non-uniform spatial behaviour, differences between each PMT gain or the deformation of the light distribution when it approaches the edge of the scintillator. These problems are alleviated by using correction maps.

However, the presence of all these phenomena in traditional detectors still reduces the intrinsic resolution and produces non-uniform compression artifacts in the image and the so called border effects. The main consequence is an unavoidable reduction of the *Useful Field Of View* (UFOV) of the PET camera, which usually covers up to 60% of each crystal dimension.

With other methods such as *Statistics Based Positioning* (SBP) or *Maximum Likelihood* (ML) positioning, this UFOV can be increased to approximately the 80% of each dimension of the crystal, but these methods involve a heavier computational cost (Joung, Miyaoka, Kohlmyer & Lewellen 2001)(Chung, Choi, Song, Jung, Cho, Choe, Lee, Kim & Kim, 2004).

These drawbacks have not been fully overcome yet. Therefore, our proposal to introduce ANNs in the detection process as good quality estimators is well-grounded.

Some previous research has been made in this area for PMT (A.M. Bronstein, M.M. Bronstein, Zibulevsky & Zeevi, 2003) and Avalanche Photodiode (APD) based (Bruyndockx, Léonard, Tavernier, Lemaître & Devroede, 2004) detectors using neural networks. In this work, the detectors are based on continuous scintillators and Multi-Anode PMTs (MA-PMTs) employing charge division read-out circuits (Siegel, Silverman, Shao & Cherry, 1996).

ANN APPROACH TO 2D POSITIONING IN PET

Materials and Methods

We have employed the GEANT4 (Agostinelli, 2002) simulation toolkit to model the detector and to generate realistic inputs for the NN. The electronic read-out of the resistor circuit was performed with SPICE analysis. The supervised training and validation of the ANNs have been carried out with the MATLAB Neural Networks

Toolbox (The Mathworks, Inc., 2004). We have chosen the RPROP algorithm (Riedmiller & Braun, 1993) because it proved to converge faster than the standard gradient descent algorithm and other variants such as the Levenberg-Marquardt algorithm. Radial basis (RB) networks were also considered but were discarded in the end due to their inferior performance.

Detector Characteristics

The model of the detector under study comprises a $49 \times 49 \times 10 \text{ mm}^3$ continuous slab of LSO scintillator crystal coupled to a Hamamatsu H8500 Flat-Panel MA-PMT. The read-out electronics is a conventional DPC-like resistive charge division circuit that proves to model Anger's logic accurately. Taking the resistor network pattern used by Aliaga et al. (Aliaga, Martínez, Gadea, Sebastián, Benlloch, Sánchez, Pavón & Lerche, 2006) as a starting point, we have designed a new resistor network based on the architecture proposed by S. Siegel (Siegel, Silverman, Shao & Cherry, 1996) (Fig. 1) that allows us to estimate the 2D positioning with better results. As in the previous design, all 64 channels (one per anode of the H8500) are coded into only 4 output lines, which are then fed into current sensitive preamplifiers. The current-ratio matrices A, B, C and D corresponding to each output were obtained from electronic read-out using SPICE analysis. The network was analyzed applying the superposition theorem for electric circuits.

Figure 1. Siegel's DPC diagram

Neural Networks

Given a collimated source S of γ photons with origin at (x_s, y_s, z_s) emitting perpendicularly to the detector surface, we can describe the interaction of a photon in the detector as a random variable $X \rightarrow \mathbf{A}$, being, \mathbf{A} a vector of elements a_i , the number of photoelectrons arriving at each anode of the MA-PMT. Thus, the elements of the vector \mathbf{J} are the inputs of the NN, which can be written as

$$J_k = \sum_i A_i \cdot G_i \cdot R_{i,k} \quad (1)$$

where J_k is the k th output of the charge division network, G the vector of pad gains of the MA-PMT (in our case randomly distributed between 1 and 3) and

$R_{i,k}$ the transfer function of the DPC from the i th anode to the k th output of the resistors network.

The Universal Approximation Theorem (Haykin, 1999) claims that any continuous function, defined over a determined region, can be approximated uniformly, with arbitrary precision, by a Multi-Layer Perceptron (MLP) of two hidden layers. Then, our position estimator can be expressed as

$$\hat{\mathbf{r}} = \Phi \{ \mathbf{J}; \mathbf{W}, b \}$$

being \mathbf{W} and b the weights and biases of each neuron of the NN. In order to adapt the NN estimator to a function f , we begin from a training set composed of pairs (J_i, X_i) where $X_i = (x_i, y_i)$ is the position of the source and $J_i = f(X_i)$ is a realization of the outputs of the charge division network for an interaction with origin at position X_i . Thus, the weights and biases of the NN are modified following a gradient descent algorithm (*backpropagation*) to minimize the mean squared error

$$E = \frac{1}{2} \sum_i \|X_i - F(J_i)\|^2$$

where F is the transfer function of the NN. Initial values of weights and biases are usually determined following the Nguyen-Widrow rule (Nguyen & Widrow, 1990).

Optimization

The detector surface was partitioned in 49×49 positions of 1 mm^2 each. An amount of 1000 valid events were generated on each position using GEANT4. Of these 1000 events, 500 were used to compose training subsets and the remaining 500 to compose test subsets, as depicted in Figure 2.

For each network architecture, 20 different trainings were averaged, each one with different initial weights and arbitrary gains for each anode. The number of epochs was fixed to 800 to ensure convergence in all cases. We preferred not to use cross-validation as there was no scarcity of patterns to train the network. The chosen activation function was the hyperbolic tangent (*tanh*).

We reduced our study to MLPs of two hidden layers. A third layer would only increase complexity without showing any significant improvement. Our analysis showed that an increment on the number of neurons in the second hidden layer improves the linearity of the response, reducing the systematic error, while an increase in the number of neurons in the first hidden layer improves the spatial resolution.

There are two different approaches for 2D positioning: a single NN with 4 inputs and 2 outputs, or two independent NNs for 1D positioning on each axis. For the first scheme, we have simulated MLPs with two

Figure 2. Methodology to obtain the training/test subsets

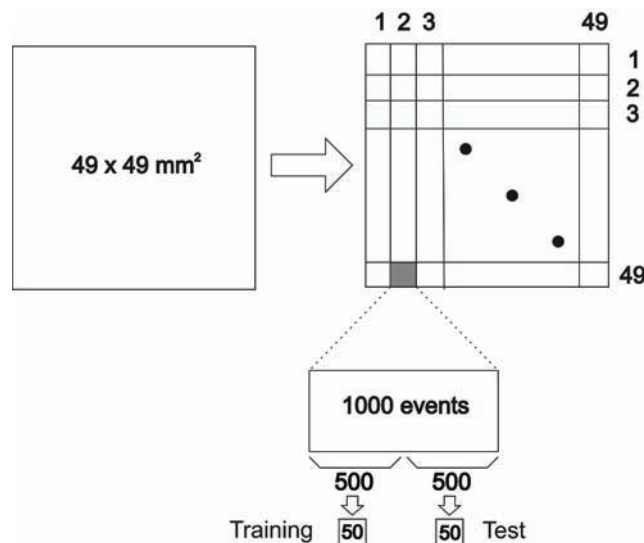

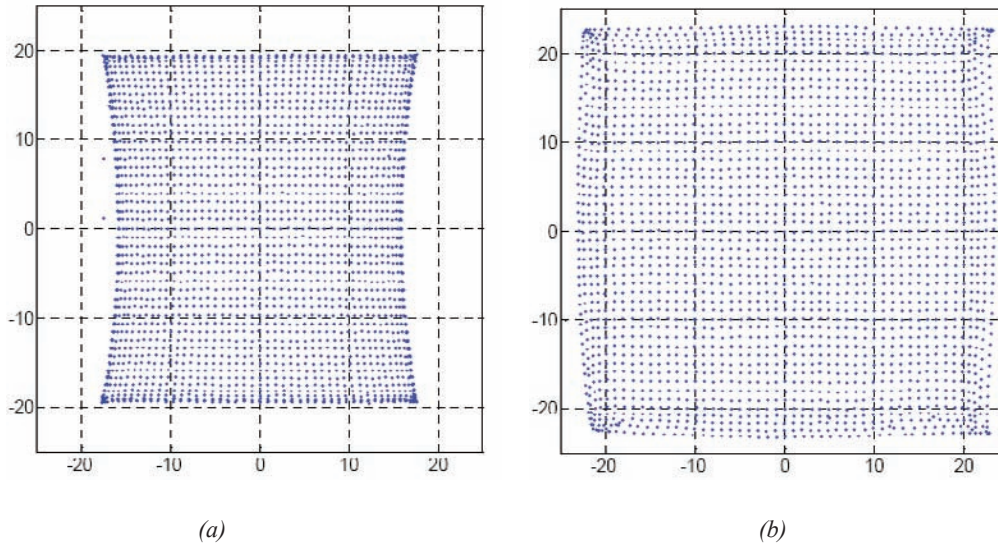

Figure 3. 2D positioning histogram for (a) centroid (Anger) based estimator and (b) NN estimator, using a 49x49 grid with 1 mm spacing

hidden layers and up to 25 hidden neurons (considering $N_1 + N_2 \leq 25$, and $N_1 > N_2$, where N_1 is the number of neurons in the first hidden layer and N_2 is the number of neurons in the second one. Thus, the NN architectures are represented as: number of inputs/ N_1 / N_2 /number of outputs) to prevent overtraining.

Results

The optimum network architecture found using a single MLP was 4/15/8/2. However, the best results were achieved with the double MLP estimator, with a 4/9/6/1 architecture, reaching a mean systematic error below 0.4 mm at almost all the detector FOV.

In Fig. 3, we can observe a 2D positioning histogram for a grid of 49x49 points separated 1 mm both using a centroid estimator (a) and a NN estimator (b).

The figure clearly shows that the centroid approach introduces non-uniform compression artifacts in the borders of the crystal, while the NN estimator successfully corrects these artifacts and produces a more uniform FOV in both dimensions. This improvement is quite significant as the UFOV increases from $30 \times 30 \text{ mm}^2$ to $40 \times 40 \text{ mm}^2$, which means approximately a 90% of the MA-PMT effective area for normal incidence (Mateo, Aliaga, Martínez, Monzó & Gadea, 2007).

FUTURE TRENDS

It would be desirable to develop a method to extend this approach to Depth Of Interaction (DOI) estimation, especially to deal with oblique incidence. With this objective, additional work is being carried out by our group (Lerche, Benlloch, Sánchez, Pavón, Giménez, Fernández, Giménez, Escat, Cerdá, Martínez & Sebastián, 2005). This would add a fifth input, Z, to the ANN, which would enable a very accurate and fully 3D reconstruction of the interaction point within the scintillator.

It would also be interesting to implement the ANN training on a hardware platform, to perform fast on-site trainings to and to enable us to calibrate the PET instrumentation automatically.

And last, but not least, we are working on a high precision testbench (Fig. 4), which has recently been presented in the Real Time Conference 2007 (Monzó, Aliaga, Herrero, Martínez, Mateo, Sebastián, Mora, Benlloch & Pavón, 2007), allows to link several simulation tools for each part of the PET system, enabling us to model the effects of the electronics in each part of the design separately. In this setup, there are separate analog and digital parts. The analog part is composed by an Application Specific Integrated Circuit (ASIC),

Figure 4. Block diagram of the high precision testbench under development

and it includes an implementation of our DPC. The digital part consists of a Field Programmable Gate Array (FPGA) board, where the neural network is going to be embedded, among other elements related to signal processing. In addition to that, we intend to install a radioactive source to obtain real stimuli instead of our current synthetic data.

CONCLUSION

ANNs have proved to be good position estimators for PET, and an interesting alternative to traditional Anger logic. The benefits of using ANN-based position estimators include lower systematic errors, and also lower standard deviations of the systematic error, increased UFOV (up to 90% of the MA-PMT effective area, for normal incidence), less compression artifacts on the crystal borders and slightly better spatial resolution, especially on the borders.

Regarding the DPC circuit, it allowed a reduction of complexity both in terms of number of variables and in terms of hardware resources.

KEY TERMS

Anger Logic: A classic procedure to obtain the position of incidence of a photon on the scintillator crystal, which requires connecting the photomultiplier outputs to a resistive network to obtain only four outputs. With these signals, the position of the scintillation centroid is easily obtained using a simple formula. This method is acceptable in the central area of the crystal but it introduces a considerable error near its borders.

Depth Of Interaction (DOI): Depth inside the scintillator crystal where a photon interacts and produces a light distribution. Its 2D coordinates coincide with those of the incidence point for normal incidence but they differ slightly for oblique incidence. Therefore, its determination is vital for oblique incidence cases.

Discretized Positioning Circuit (DPC): An analog resistive network that receives a large amount of currents and “codes” them into a reduced number of them, introducing a minimum delay. These new currents are linear combinations of those generated by the photodetectors.

Gamma Camera: A camera that detects gamma rays (often called Anger camera).

Multi-Layer Perceptron (MLP): A kind of feed-forward neural network which has at least one hidden layer of neurons.

Neural Network: A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in applications such as robotics, speech recognition, signal processing or medical diagnosis.

Photomultiplier Tube (PMT): A part of the PET detector that receives the electromagnetic energy from the scintillator crystal and transforms that energy into electric pulses. This conversion is done in two stages: firstly the photons are absorbed, producing free electrons, and secondly a cascade amplification takes place.

Positron Emission Tomography (PET): PET is a nuclear imaging technique based on the administration of radioactive substances (radiotracers), whose molecules have a radioactive isotope (radionuclide), to a patient under study, with the aim to trace some chemical or physiological process that takes place in the body, typically for diagnosis of heart diseases, cancer, etc. The images obtained in a PET system are 2D sections of the concentration distribution of a radiotracer inside the body. When joining these sections, a medical 3D image can be obtained.

Scintillator Crystal: When a particle interacts inside a scintillator crystal, it deposits energy. The scintillator crystal re-emits part of that energy as photons in the visible spectrum. To allow this light to be measured from the outside, the crystal must also be transparent to that light. This is done by doping the crystal so that permitted states are created in the forbidden band of the material.

Useful Field of View (UFOV): Area of the scintillator crystal surface on which the incidence of gamma rays produces reasonable estimations of the position of incidence.

2D–PAGE Analysis Using Evolutionary Computation

INTRODUCTION

This paper presents the preliminary studies for the creation of a new tool to assist in medical diagnostic. The tool will help in the analysis of 2D-PAGE images. In order to create a 2D-PAGE image of an ideal patient—the patient could be healthy or ill—the tool will help us in the creation of an image that facilitates and speeds up future diagnostics. The creation of a master image has motivated the development of a tool to alignment gel images. The tool will make easier the correspondence among the proteins into the ideal image and the ones of a new image. Due to the fact that image registering process is quite complex, we use the Intel's library OpenCV which provides functions to calculate optical flow and translation vectors.

This library introduces into the project a set of variables unknown by the facultative. To solve this, an automatic selection of values for this set of variables is necessary. This last task is made with the Evolutionary Computation technique called Particle Swarm Optimization (Kennedy, R. & Eberhart, J. 1995)

BACKGROUND

In the 20th century medicine, the number of medical images has been growing. X-ray photographs, magnetic resonances, 2D gels images, angiographies can be taken as examples. The major difficulty for the physician is to integrate all this information in order to offer a diagnosis.

This way, since computers started being used for analyzing and treating images at the end of the 20th century, one of the most important fields inside the application of computers to image processing has been the treatment of all medical existing images. It is here where technologies of Evolutionary Computation and Neural Networks are necessary, because they facilitate certain processes of adjustment that, in another way, would be extraordinarily complex or laborious. Among the most usual technologies used for the processing of biomedical images there can be pointed out Artificial Neural Networks, Genetic Algorithms, Particle Swarm Optimization, Splines or Growth of Regions.

Amongst some examples, we can emphasize the use of Artificial Neural Networks for the analysis of radiological images, Genetic Algorithms (Holland, J.H., 1975) in the 3D reconstruction of anthropologic models (Santamaría, J., Cordon, O., Damas, S., Alemán, I., Botella, M., 2006) and in the integration of the information obtained by means of different methods—Computed Tomography (CT), Magnetic Resonance Imaging (MRI),...—(Rouet, J. M., Jacq. J. J., Roux, C., 2000), Particle Swarm Optimization for alignment of 2D and 3D biomedical images (Wachowiak, M. P., Smolikova, R., Zheng, Y., Zurada, J. M., Elmaghraby, A. S., 2004) or the use of Splines to 2D-PAGE registering (Seow, N., Sowmya, A., Sun, C., 2005).

In our case, the technology to use will be the Particle Swarm Optimization dedicated to improve the analysis of 2D-PAGE (Seoane, J. A., Mesejo, P., Ruiz-Romero, C., Dorado, J., Pazos, A., Blanco, F. J., 2007).

PSO APPLIED TO THE OPTIMIZATION OF OPENCV PARAMETERS FOR 2D-PAGE ANALYSIS

The aim of this investigation is to help the doctors in process of identification of certain characteristics in the 2D-PAGE images (Ruiz-Romero, C., López-Armada, M. J., Blanco, F. J., 2005). In order to do that the registry image process will consist on the alignment between the master image, which has been labelled for every protein, and an image whose interesting points have been identified by the facultative to study. This registry process will make easier to the medical the study of the presence or absence of a certain kind of protein and its concentration.

2D-PAGE

This work uses the images called 2D-PAGE—*polyacrylamide gel electrophoresis*. The process to obtain these images uses the electrophoresis, which is a well known analytic technique for macromolecules—DNA or Protein—separation. The responsible of this separation is the mobility presented by the electrically charged macromolecules when a differential voltage is applied. The method tries to immobilize the studying molecules into a gelatinous material; in this case the material will be polyacrylamide. This process was well described by (Bueno García, G. 2005) as “A differential voltage is applied to the gel with the biological samples inside during a concrete period of time. Each molecule will migrate through the gel pores with a different speed, which is dependent of the electrical charge and the mass of each molecule.”

On one hand, the resultant gels are classified on X-axis on respect the isoelectric point—PH to which an amphoteric substance has no voltage. On the other hand, on Y-axis gels are sorted by their molecular mass.

The resultant image will help us to detect the presence or absence of a certain protein, or even the more or less protein concentration. This information will assist us to know the existence or inexistence of some illness or characteristic.

OpenCV

OpenCV is an open source library which has been developed in C++ for Computer Vision. This library is optimized to be applied in real time problems inde-

pendently of the platform. It is especially oriented to images manipulation and processing and also to the movement analysis into the image. Some interesting information about this library could be found at (Agam, G., 2006).

To solve the problem, one of the Optical Flow functions, which can be found in the OpenCV library, was used. Specifically we use the function known as *CalcOpticalFlowBM*. This function divides two images into blocks, in order to find the same block of the first one in the second image. After this search process, the function establishes a set of movement vectors which corresponds to the movements of the blocks of the image. For more information about this topic visit (Department of Electrical Engineering, Nara National College of Technology's Web Page, 2006) and (Intel's Web Page).

This function is very useful in our problem because we need an alignment image tool for the creation of the proteomic diagnostic image. When we try to align two images, a function that compares these two images and tells us the movement among them will be useful. This function searches the similarities using the statistical correlation among sets of pixels of the two images. The new protein location process will only need the movement vector and the block of that spot.

The function *CalcOpticalFlowBM* has a set of parameters, the ones to be optimized are:

- **blockSize:** the size of comparable blocks in which the image is divided.
- **maxRange:** neighborhood maximum size around a block that would be explore to find the block in the second image.

These parameters will be optimized with an artificial intelligence technique, because, in other case, this process will be done manually by the user.

Particle Swarm Optimization

The Evolutionary Computation technique that has been used in this work is the Particle Swarm Optimization (PSO). Inspired on the social swarm from nature, was developed by Kennedy and Eberhart (Kennedy, J. & Eberhart, R., 1995). In a PSO algorithm a particle swarm explores the search space. Each particle represents a possible solution to the optimization problem. The position of each particle is the result of the best position

visited by the particle—self experience—and the best position of its neighborhood—its social experience. When the particle's neighborhood is the whole swarm, the best particle in the neighborhood is the best global position; the resulted algorithm is called *gBest* PSO. When smaller neighborhood size is used, the algorithm is called *lBest* PSO. The fitness of each particle—how far from the optimum is—is calculated using a function that varies with the concrete optimization problem.

Each particle is represented into swarm by:

- x_i : particle's current position.
- v_i : particle's current speed.
- y_i : particle's best self-position

Particle's best self-position for an i element is the best position visited by the particle. If f is the objective function then the best self-position in a time t is updated as (Ec.1):

$$y_i(t+1) = \begin{cases} y_i(t), & \text{if } f(x_i(t+1)) \geq f(y_i(t)) \\ x_i(t), & \text{if } f(x_i(t+1)) < f(y_i(t)) \end{cases} \quad (1)$$

If the particle's best global position is denoted by the vector \hat{y} then:

$$\hat{y}(t) \in \{y_0, y_1, \dots, y_s\} = \min \{f(y_0(t)), f(y_1(t)), \dots, f(y_s(t))\} \quad (2)$$

where s denotes the swam size. Taking *lBest* with N_j neighborhoods in which the best neighborhood's particle is denoted by \hat{y}_j , that particle will be known as the best neighborhood's particle and is defined by:

$$\hat{y}_j(t+1) \in \{N_j \mid f(\hat{y}_j(t+1)) = \min \{f(y_i(t))\}, \forall y_i \in N_j\} \quad (3)$$

where

$$N_j = \{y_{i-1}(t), y_{i-1+1}(t), \dots, y_{i-1}(t), y_i(t), y_{i+1}(t), \dots, y_{i+1-1}(t), y_{i+1}(t)\} \quad (4)$$

The neighborhoods are usually defined by the particle's index, but can be also defined by topological relations. It is easy to see that *gBest* is only a particular case of *lBest*, where the neighborhood is the whole swarm. Notice that the *lBest* produces more diversity in the solutions, but it is also true that it has a higher computation time cost than *gBest*.

For each PSO algorithm iteration, the update of speed v_i is specified for each dimension $j \in 1, \dots, N_d$, being N_d the dimension of the problem. So, v_{ij} represents the j^{th} element of the i^{th} particle's speed vector. Burning on mind this, the i particle speed is updated by the following equation:

$$v_{ij}(t+1) = wv_{ij} + c_1r_{1j}(t)(y_{ij}(t) - x_{ij}(t)) + c_2r_{2j}(t)(\hat{y}_j(t) - x_{ij}(t)) \quad (5)$$

the most important terms are:

- *Learning rates (weights)*, c_1 and c_2 , which determine the influence of the learning components, cognitive versus social.
- $r_{1j}, r_{2j} \sim U(1,0)$, these components introduce the randomness into the algorithm.
- The term inertia component, w , is used to control the influence of the previous speed. High values of this term increase the global exploration; however, low values increase the local exploitation.
- The cognitive component, $y_i(t) - x_i(t)$, represents the particle's self-experience to find the better solution.
- The social component, $\hat{y}(t) - x_i(t)$, represents the swarm knowledge about the better solution.

The position of particle i , x_i , is updated using the equation 6:

$$x_i(t+1) = x_i(t) + v_i(t+1) \quad (6)$$

The PSO algorithm applies repeatedly the update equations, which have been described previously. Until a number of iterations is exceeded, the update speeds are near 0. The fitness value of the function gives us the quality of the solution.

In concrete the PSO algorithm that has been used to optimize the OpenCV parameters is a complete model. The values of c_1 and c_2 are not zero and then the social and cognitive components are taken into account. Finally, to comment that these values were fixed to the test in the value of 2 as is recommended in (Kennedy, J. and Mendes, R., 2006). The inertia weights are fixed between the values 0,8 and 1,2 (Eberhart, R. and Shi, Y., 2000).

For more information about PSO the following papers could be consulted: (Omran, M.G., Engelbrecht, A.P. and Salman A., 2005) and (Kennedy, J., Eberhart, R. C., and Shi, Y., 2001).

Combining all Elements

The PSO algorithm is used, in this case, to establish the block size and the search area in the images. To do that we try to minimize the intensity differences of each pixel for every couple of blocks considerate as equals.

When the PSO will have ended we will have the optimus parameter configuration to the OpenCV function.

Some examples of this application are in Figure 1.

In the previous left figure we can see the image of a new gel to analyze, from which interests to us the three red remarked proteins. After the application of block matching technique and optimizing the OpenCV parameters with the PSO system, we obtain the correct position of the proteins on the master image, as we can see in the central image.

FUTURE TRENDS

After the correct location of the protein, by means of the already seen technologies, the main future aim would consist on the integration of the intensity of the protein in the master image. A possible way of integrating the new proteins in the master would be to use the alpha channel (transparency of the image) so that the fragment of the image to integrate had the values corresponding to the alpha level to one and those of the target image to zero, thereby this fragment would join the target image. With the intention of the integration process being as smooth as possible in the edges of spot integrated; one degraded will be realized by means of a low pass filter. The low pass filter emphasizes the Low Frequencies, smoothes images and noises, reducing the variability of the image. A median filter could be used to make this smoothing, this filter is less sensible to extremely asides values. Also the degraded could be made manually, choosing a size of window that includes the interest point, so that the degraded between the margin of the window and the limit of the point was proportional to the distance to the spot.

The final aim would be, by means of some technology of artificial intelligence (Artificial Neural Networks or Expert Systems), to advise the doctor in the diagnosis, for which, obviously, the previous tool should have been calibrated and adjusted correctly.

Figure 1. (Left) New gel; (center) master; (right) new gel with the intermediately step

CONCLUSION

The first thing that we can extract after this work is that technologies of Evolutionary Computation can be used to assist in medical decision. This way, it has been proved that by means of these technologies, a support has been realized in the identification of certain interesting points. This is useful for the doctors since they will not have to know the functioning of the tool of computation, in particular the parameters that control the function of the library that executes the alignment.

Besides, these technologies of computation do not obtain a unique adjustment but a set of these, which will allow to choose the best result from the point of view of the user.

KEY TERMS

Amphoteric Substance: Substance is one that can react as either an acid or base.

Area of the Search Space: Set of specific ranges or values of the input variables that constitute a subset of the search space.

Artificial Neural Networks: System composed of many simple processing elements operating in parallel whose function is determined by network structure, connection strengths, and the processing performed at computing elements or nodes.

Electrophoresis: Separation of molecules (proteins or nucleic acids) in an electric field as a function of their molecular weight and/or their electric charge.

Evolutionary Computation: Generic term used to indicate any population-based metaheuristic optimization algorithm that uses mechanisms inspired by biological evolution (Darwin, D., 1859) (Wallace, A. R., 1858), such as reproduction, mutation and recombination.

Genetic Algorithm: An algorithm for optimizing a property based on an evolutionary mechanism that uses replication, deletion, and mutation processes carried out over many generations. (Goldberg, D.E., 1989) (Fogel, L.J., Owens, A.J. & Walsh, M.A. 1966)

Particle: Each of the elements that explore the search space in a Particle Swarm Optimization algorithm.

Particle Swarm Optimization: Evolutionary Computation technique that basis its functioning on natural swarm behaviour like the birds. This algorithm uses a swarm of particles to explore the search space

Polyacrylamide: Acrylate polymer formed from acrylamide subunits that is readily cross-linked.

Protein: A molecule composed of a long chain of amino acids. Proteins are the principal constituents of cellular material

Search Space: Set of all possible situations of the problem that we want to solve could ever be in.

Visualizing Cancer Databases Using Hybrid Spaces

INTRODUCTION

According to the World Health Organization (WHO), the directing and coordinating authority for health within the United Nations system <http://www.who.int/cancer/en/>, from a total of 58 million deaths in 2005, cancer accounts for 7.6 million (or 13%) of all deaths worldwide. This places cancer as one of the leading causes of death in the world, with lung cancer (the main cancer leading to mortality) accounting for 1.3 million deaths per year. Thus the importance of understanding the mechanisms of lung cancer is clear. One approach is through the rapid quantification of the gene expression levels of samples of healthy and diseased lung tissue. This new field blending the knowledge from biologists, computer scientists and mathematicians is known as Bioinformatics and is yielding large quantities of data of a very high dimensional nature that needs to be understood.

BACKGROUND

The increasing complexity of the data analysis procedures makes it more difficult for the user (not necessarily a mathematician or data mining expert), to extract useful information out of the results generated by the various techniques. This makes graphical representation directly appealing; for which Virtual Reality (VR) is a suitable paradigm. Virtual Reality is *flexible*; it allows the construction of different virtual worlds representing *the same* underlying information, but with a different look and feel. VR allows *immersion*, that is, the user can navigate inside the data, interact with the objects in the world. VR creates a *living* experience. The user is not merely a passive observer but an actor in the world. VR is *broad and deep*. The user may see the VR world as a whole, and/or concentrate the focus of attention on

specific details of the world. Of no less importance is the fact that in order to interact with a Virtual World, no mathematical knowledge is required, and the user only needs minimal computer skills. A virtual reality technique for visual data mining on heterogeneous, imprecise and incomplete information systems was introduced in (Valdés, J.J., 2002) (Valdés, J.J., 2003) (see also <http://www.hybridstrategies.com>).

The purpose of this article is to explore the construction of high quality VR spaces for visual data mining (in opposition to classical data mining (Fayyad, U., Piatesky-Shapiro, G., & Smyth, P., 1996)) using a multi-objective optimization technique applied to the understanding of a publicly available lung cancer gene expression data set. This approach provides both a solution for the previously discussed problem, and the possibility of obtaining a set of spaces in which the different objectives are expressed in different degrees, with the proviso that no other spaces could improve any of the considered criteria individually (if spaces are constructed using the solutions along the Pareto front). This strategy represents a conceptual improvement in comparison with spaces computed from the solutions obtained by single-objective optimization algorithms in which the objective function is a weighted composition involving different criteria.

THE MULTI-OBJECTIVE APPROACH: A HYBRID PERSPECTIVE

In order to establish a formulation of the problem based on multi-objective optimization, a set of objective functions has to be specified, representing the corresponding criteria that must be simultaneously satisfied by the solution. The minimization of a measure of similarity information loss between the original and the transformed spaces and a classification error measure

over the objects in the new space can be used in a first approximation. Clearly, more requirements can be imposed on the solution by adding the corresponding objective functions. Following a principle of parsimony this paper will consider the use of only two criteria, namely, Sammon's error (Sammon, J.W., 1969) for the unsupervised case and mean cross-validated classification error with a k -nearest neighbour pattern recognizer for the supervised case.

The proximity (or similarity) of an object to another object may be defined by a distance (or similarity) calculated over the independent variables and can be defined by using a variety of measures. In the present case a normalized Euclidean distance is chosen:

$$d_{\frac{x}{t}} = \sqrt{(1/p) \sum_{j=1}^p (x_{ij} - t_{kj})^2} \quad (1)$$

Structure Preservation: An Unsupervised Perspective

Examples of error measures frequently used for structure preservation (Kruskal, J., 1964) (Sammon, J.W., 1969) (Borg, I., & Lingoes, J., 1987) are:

$$S \text{ stress} = \sqrt{\frac{\sum_{i < j} (\delta_{ij}^2 - \zeta_{ij}^2)^2}{\sum_{i < j} \delta_{ij}^4}}, \quad (2)$$

$$\text{Sammon error} = \frac{1}{\sum_{i < j} \delta_{ij}} \frac{\sum_{i < j} (\delta_{ij} - \zeta_{ij})^2}{\delta_{ij}} \quad (3)$$

$$\text{Quadratic Loss} = \sum_{i < j} (\delta_{ij} - \zeta_{ij})^2 \quad (4)$$

For heterogeneous data involving mixtures of nominal and ratio variables, the Gower similarity measure (Gower, J.C., 1973) has proven to be suitable. The similarity between objects i and j is given by

$$S_{ij} = \sum_{k=1}^p s_{ijk} / \sum_{k=1}^p w_{ijk} \quad (5)$$

where the weight of the attribute (w_{ijk}) is set equal to 0 or 1 depending on whether the comparison is consid-

ered valid for attribute k . If $v_{k(i)}$, $v_{k(j)}$ are the values of attribute k for objects i and j respectively, an invalid comparison occurs when at least one them is missing. In this situation w_{ijk} is set to 0.

For quantitative attributes (like the ones of the datasets used in the paper), the scores s_{ijk} are assigned as

$$s_{ijk} = 1 - |v_k(i) - v_k(j)| / R_k$$

where R_k is the range of attribute k . For nominal attributes

$$s_{ijk} = \begin{cases} 1 & \text{if } v_k(i) = v_k(j) \\ 0 & \text{otherwise} \end{cases}$$

This measure can be easily extended for ordinal, interval, and other kind of variables. Also, weighting schemes can be incorporated for considering differential importance of the descriptor variables.

Multi-Objective Optimization Using Genetic Algorithms

An enhancement to the traditional evolutionary algorithm (Bäck T., Fogel, D.B., & Michalewicz, Z., 1997), is to allow an individual to have more than one measure of fitness within a population. One way in which such an enhancement may be applied, is through the use of, for example, a weighted sum of more than one fitness value (Burke, E.K., & Kendall, G., 2005). Multi-objective optimization, however, offers another possible way for enabling such an enhancement. In the latter case, the problem arises for the evolutionary algorithm to select individuals for inclusion in the next population, because a set of individuals contained in one population exhibits a Pareto Front (Pareto, V., 1896) of best current individuals, rather than a single best individual. Most (Burke, E.K., & Kendall, G., 2005) multi-objective algorithms use the concept of dominance to address this issue.

A solution $x_{(1)}$ is said to dominate (Burke, E.K., & Kendall, G., 2005) a solution $x_{(2)}$ for a set of m objective functions $\langle f_1(x), f_2(x), \dots, f_m(x) \rangle$ if

- $x_{(1)}$ is not worse than $x_{(2)}$ over all objectives. For example, $f_3(x_{(1)}) \leq f_3(x_{(2)})$ if $f_3(x)$ is a minimization objective.

- $x_{(1)}$ is strictly better than $x_{(2)}$ in at least one objective. For example, $f_6(x_{(1)}) > f_6(x_{(2)})$ if $f_6(x)$ is a maximization objective.

One particular algorithm for multi-objective optimization is the elitist non-dominated sorting genetic algorithm (NSGA-II) (Deb, K., Pratap, A., Agarwal, S., & Meyarivan, T., 2000), (Deb, K., Agarwal, S., Pratap, A., & Meyarivan, T., 2000), (Deb, K., Agarwal, S., & Meyarivan, T., 2002), (Burke, E.K., & Kendall, G., 2005). It has the features that it *i*) uses elitism, *ii*) uses an explicit diversity preserving mechanism, and *iii*) emphasizes the non-dominated solutions.

Original Study

Gene expressions were compared in (Spira, A., Beane, J., Pinto-Plata, V., Kadar, A., Liu, G., Shah, V., Celli, B., & Brody, J.S., 2004) for severely emphysematous lung tissue (from smokers at lung volume reduction surgery) and normal or mildly emphysematous lung tissue (from smokers undergoing resection of pulmonary nodules). The original database contained 30 samples (18 severe emphysema, 12 mild or no emphysema), with 22,283 attributes. Genes with large detection P-values were filtered out, leading to a data set with 9,336 genes that were used for subsequent analysis. Nine classification algorithms were used to identify a group of genes whose expression in the lung distinguished severe emphysema from mild or no emphysema. First,

model selection was performed for every algorithm by leave-one-out cross-validation, and the gene list corresponding to the best model was saved. The genes reported by at least four classification algorithms (102 genes) were chosen for further analysis. With these genes, a two-dimensional hierarchical clustering using Pearson's correlation was performed that distinguished between severe emphysema and mild or no emphysema. Other genes were also identified that may be causally involved in the pathogenesis of the emphysema. Data was from: http://www.ncbi.nlm.nih.gov/projects/geo/gds/gds_browse.cgi?gds=737.

Experimental Settings

Each sample in this study is a vector in a high dimensional space, and therefore, direct inspection of the structure of this data, and of the relationship between the descriptor variables (the genes) and the type of sample (normal or cancer), is impossible. Moreover, within the collection of genes there is a mixture of potentially relevant genes with others which are irrelevant, noisy, etc. The need of simultaneously finding a visual representation (3D) respecting (as much as possible) the set of object interrelationships as defined by the original attributes, and the construction of a new feature space effectively differentiating the two classes of objects present, makes this problem suitable for a multi-objective optimization approach.

Table 1. Experimental settings for computing the pareto-optimal solution approximations by the multi-objective genetic algorithm (PGAPack (Levine, D., 1996) extended by NSGA-II).

| | | | |
|---|--|---|------------|
| population size | 100 | number of generations | 500 |
| chromosome length | 90 (= 3 · 30) | ga seed | 101 |
| No. new inds. in (<i>i</i> + 1st) pop. | 20 | objective functions should be minimized | |
| chromosome data representation | real | crossover probability | 0.8 |
| crossover type | uniform (prob. 0.6) | mutation probability | 0.4 |
| mutation type | gaussian | selection type | tournament |
| tournament probability | 0.6 | mutation and crossover | yes |
| population initialization | random, bounded | lower bound for initialization | -2 |
| upper bound for initialization | 2 | fitness values | raw |
| stopping criteria | maximum iterations | restart ga during execution | no |
| parallel populations | no | | |
| number of objectives | 2 | number of constraints | 0 |
| pre-computed diss. matrix | Gower dissimilarity | | |
| evaluation functions | mean cross-validated k-nn error and Sammon error | | |
| cross-validation (c.v.) | 5 folds | randomize before c.v. | yes |
| knn seed | 101 | k nearest neighbors | 3 |
| non-linear mapping measure | Sammon | dimension of the new space | 3 |

The collection of parameters describing the application of the NSGA-II algorithm is shown in Table-1. A modest population size and number of generations were used, with a relatively high mutation probability in order to enable richer genetic diversity. Randomization of the set of data objects was applied in order to reduce the bias in the composition of the cross-validated folds by providing a more even class distribution between successive training and test subsets. The number of folds was set in consideration of the sample size.

Results

The set of non-dominated solutions obtained by the NSGA-II algorithm is shown in the scatter plot of Fig-1(a), where the horizontal axis is the mean cross-validated knn error and the vertical axis the Sammon error. The approximate location of the Pareto front is defined by the convex polygon joining the solutions provided by chromosomes 2, 1, 10, etc. Chromosome 2 defines a space with a perfect resolution of the supervised problem in terms of the “*no or mild emphysema*” and “*severe emphysema*” classes (knn error =0), but at the cost of a severe distortion of the space. Whereas, chromosome 1 approximates a pure unsupervised solution (with low Sammon error). Its classification error is large indicating that few non-linear features preserving the similarity structure lacks classification power. This may be due to the large amount of attribute noise, redundancy, and irrelevancy within the set of 22,283 original genes.

Clearly, it is impossible to represent virtual reality spaces on a static medium. However, a composition of snapshots of the VR spaces using the solutions along the Pareto front approximation is shown in Fig-1(b-d). Different mappings (even with important differences from the point of view of the mapping error) lead to similar 3D visual representations, which indicate good solution reproducibility. The similarities are associated to the main distributions of the clouds of points, which are preserved, while there might be local discrepancies with respect to the placement of some objects.

A solution satisfying classification error as much as possible (actually with 0-error) is shown in Fig-1(b) where both classes are separated into 2 main clouds of points and a distinct point, Object 6, positioned separately from the clouds. It can be seen that Object 6 is positioned relatively differently in the spaces that comprise the best Sammon error Fig-1(d) and trade-offs

between the classification error objective and Sammon error objective Fig-1(c). This is why, visually, the latter space represents a compromised solution between the two goals and why it is a trade-off between the two objective functions. It should be remembered that the class information is not used at all for computing the spaces. Chromosome 10, according to Fig-1(a) and Fig-1(c), can be considered to be the best multi-objective compromised solution in which both error criteria are simultaneously as low as possible. It shows reasonable class discrimination with a non-large similarity structure distortion, which is a very meaningful result.

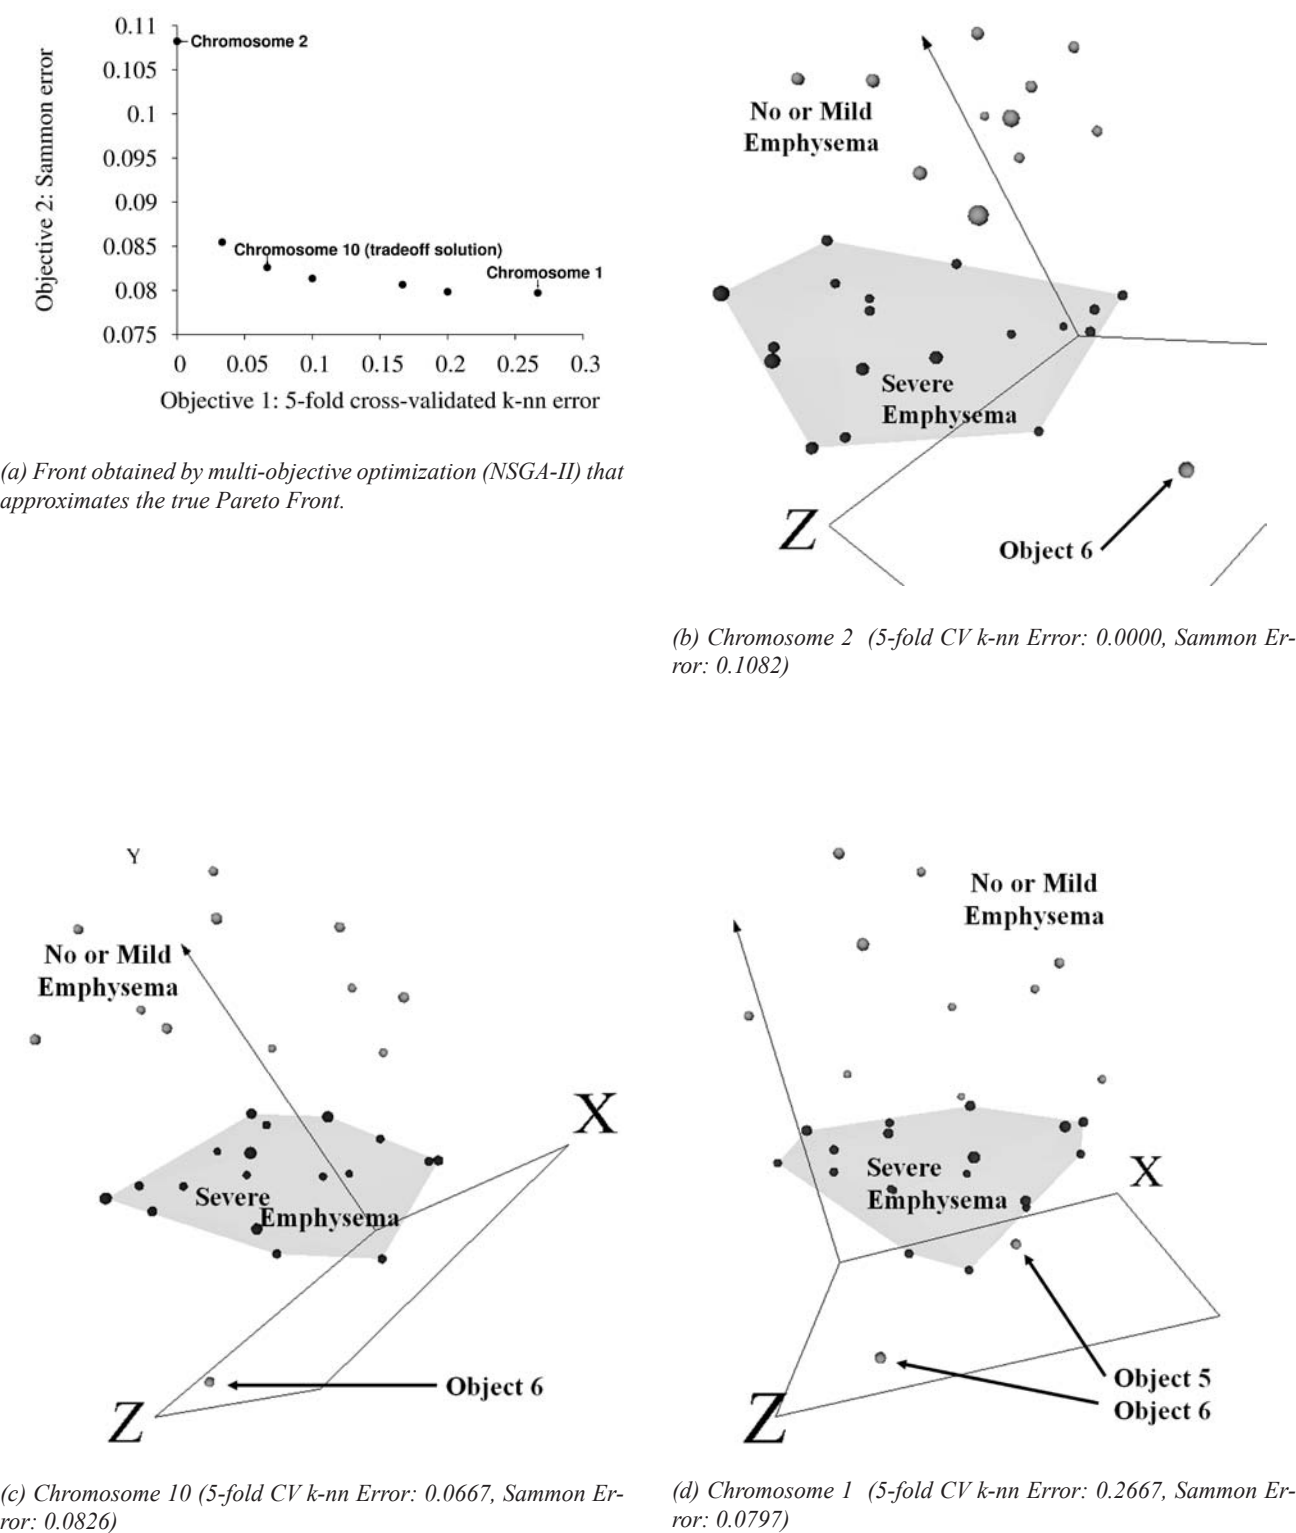

FUTURE TRENDS

Visualization of data is of potential interest for various research communities and the authors have applied various visualization approaches to other medical data diseases such as those coming from Scleroderma Skin disease, Breast Cancer, Alzheimer’s disease, and Leukemia. But, in fact, a restriction to medical data is not made by the authors, for which they have also preliminarily investigated data coming from, for example, the fields of Hydrochemistry and Geophysical Prospecting.

CONCLUSION

A multi-objective optimization approach was introduced for the problem of computing virtual reality spaces in the context of visual data mining and knowledge discovery applied to relational structures (e.g. databases). The multi-objective procedure was based on NSGA-II using two objective functions representative of unsupervised and supervised criteria (mean cross-validated knn error as a measure of miss-classification, and Sammon error as a measure of similarity structure loss). This methodology was applied to the analysis of high dimensional genomic data collected in the framework of Lung cancer research. A Pareto front approximation was recognizable from within the solutions provided by the final population. Selected solutions from along that approximation were used for the construction of a sequence of visualizations showing the progression from spaces with complete class separation and poor similarity preservation to spaces with reversed characteristics. A solution with a reasonable compromise

Figure 1. Set of 100 multi-objective solutions. Those along the Pareto front approximation progressively span the extremes between minimum classification error and minimum dissimilarity loss. 3 solutions were selected and snapshots of VR spaces computed. Geometries: “light grey spheres” = no or mild emphysema samples, “dark grey spheres encased within a convex hull” = severe emphysema samples. Behavior = static.

between the two criteria was identified and clearly contained properties of both extreme solution spaces. These research results, although preliminary, showed large potential and further investigation is required.

ACKNOWLEDGMENT

The authors would like to thank Robert Orchard from the Integrated Reasoning Group (National Research Council Canada, Institute for Information Technology) for his constructive criticism of the first draft of this paper.

KEY TERMS

Cancer: A term for diseases in which abnormal cells divide without control and can invade other tissues. Cancer cells can spread to other parts of the body through the blood and lymph systems. Cancer is not just one disease but many diseases. There are more than 100 different types of cancer. <http://www.cancer.gov/cancertopics/what-is-cancer>

Evolutionary Algorithms: A subset of evolutionary computation, which generally only involve techniques inspired by biological evolution such as reproduction, mutation, recombination, natural selection and survival of the fittest. Candidate solutions to an optimization problem play the role of individuals in a population, and

the fitness function determines the environment within which the solutions “live”. Evolution of the population then takes place after the repeated application of the above operators.http://en.wikipedia.org/wiki/Evolutionary_Computation

Gene: 1. A unit of DNA that carries information for the biosynthesis of a specific product in the cell. 2. Ultimate unit by which inheritable characteristics are transmitted to succeeding generations in all living organisms. Genes are contained by, and arranged along the length of, the chromosome. The gene is composed of deoxyribonucleic acid (DNA). Each chromosome of a species has a definite number and arrangement of genes, which govern both the structure and metabolic functions of the cells and thus of the entire organism. Genes provide information for the synthesis of enzymes and other proteins and specify when these substances are to be made. Alteration of either gene number or arrangement can result in mutation (a change in the inheritable traits).<http://www.amfar.org/cgi-bin/iowa/bridge.html?page=G>

Hybrid Space: A constructed space that attempts to preserve more than one property (possibly in conflict) of the original space. For example, preserving distances between objects and the class structure of the original space.

Multi-objective Algorithm: An optimization algorithm that attempts to find the best solutions across all measures of solution acceptability. That is, the Pareto Front is sought, even under the situation that it may not be theoretically known.

Unsupervised Algorithm: The true class that an object belongs to is not known to the algorithm; hence the algorithm is not supervised by a “teacher”. For example, clustering algorithms are unsupervised because each cluster is generated based on the data itself. Although the true class may also be known, it was not used.

Virtual Reality: (often called VR for short) Is an attempt to provide more natural, human interfaces to software. It can be as simple as a pseudo 3D interface or as elaborate as an isolated room in which the computer can control the user’s senses of vision, hearing, and even smell and touch. <http://www.saugus.net/Computer/Terms/>

Voltage Instability Detection Using Neural Networks

INTRODUCTION

The explosive growth in decision-support systems over the past 30 years has yielded numerous “intelligent” systems that have often produced less-than-stellar results (Michalewicz Z. et al., 2005). The increasing trend in developing intelligent systems based on neural networks is attributed to their capability of learning nonlinear problems offline with selective training, which can lead to sufficiently accurate online response. Artificial neural networks have been used to solve many problems obtaining outstanding results in various application areas such as power systems. Power systems applications can benefit from such intelligent systems; particularly for voltage stabilization, where voltage instability in power distribution systems could lead to voltage collapse and thus power blackouts.

This article presents an intelligent system which detects voltage instability and classifies voltage output of an assumed power distribution system (PDS) as: stable, unstable or overload. The novelty of our work is the use of voltage output images as the input patterns to the neural network for training and generalizing purposes, thus providing a faster instability detection system that simulates a trained operator controlling and monitoring the 3-phase voltage output of the simulated PDS.

BACKGROUND

Artificial Neural Networks have been used to solve many problems obtaining outstanding results in various applications such as classification, clustering, pattern recognition and forecasting among many other applications corresponding to different areas.

Power system stability is the property of a power system which enables it to remain in a state of equilibrium under normal operating conditions and to regain an acceptable state of equilibrium after a disturbance. Beyond a certain level, the decrease of power system stability margins can lead to unacceptable operating conditions and/or to frequent power system collapses (Sjostrom M. et al., 1999) (Ernst D. et al., 2004). In 2003 and within less than two months, a number of blackouts happened around the world, affecting millions of people. These blackouts include (Novosel D. et al., 2004):

- The 14th of August blackout in Northeast United States and Canada, which is considered one of the worst blackouts in the history of these countries, affecting approximately 50 million people.
- The 28th of August blackout in London, which affected commuters during the rush hour.
- The 23rd of September blackout in Sweden and Denmark, which affected approximately 5 million people.
- The 28th of September blackout in Italy, which is considered the worst blackout in Europe ever, affecting approximately 57 million people.

In recent years voltage instability has been one of the major reasons for blackouts, and it is the root cause of the 14 August blackout. Voltage stability is threatened when a disturbance increases the reactive power demand beyond the sustainable capacity of the available reactive power resources. Although, progress in the areas of communication and digital technology has increased the amount of information available at the efficient supervisory control and data acquisition

(SCADA) systems, however, during events that cause outages, an operator may be overwhelmed by the excessive number of simultaneously operating alarms, which increases the time required for identifying the main outage cause and then starting the restoration process (De Souza A.C.Z. et al., 1997) (Lukomski R. & Wilkosz K., 2003). Additionally, factors such as stress and human error can affect the operator's performance; thus, the need for an additional tool to support the real-time decision-making process which currently exists. This tool can be in the form of an intelligent voltage instability detector.

The implementation of neural networks for stabilizing power systems in general has been recently suggested (Wenxin L. et al., 2003) (Cardoso G. et al., 2004) (Keyhani A. et al., 2005) (Alcántara F.J. & Salmerón P., 2005) (Mishra, 2006). Research on different approaches to the assessment and improvement of voltage stabilization in particular has proposed different solutions to voltage instability using neural networks (Bansilal et al., 2003) (Kamalasadan S., 2006) (Lin H.C., 2007). However, none of the existing intelligent system solutions to detecting voltage instability in power distribution systems addresses the possibility of providing an artificial intelligent detector that simulates a human operator whose task is to detect voltage instability via monitoring the voltage output.

This article suggests a novel method for detecting voltage instability in power distribution systems. The proposed system uses 3-phase voltage output images as its database for training and generalizing a supervised neural network based on the back propagation learning algorithm. The intelligent system comprises two phases: the image processing phase, where voltage output images are pre-processed and meaningful features are obtained as the input patterns for the next phase which is the neural network implementation. Here, the supervised neural network learns to associate the voltage output patterns with three possible classifications; namely, Stable, Unstable or Overload.

The main objective of the proposed intelligent system is to provide earlier detection of voltage instability thus aiding a human operator. The intelligent system can be operated concurrently with SCADA systems thus enhancing the stability of the power distribution system. Upon the detection of voltage instability by the intelligent system, further measures can be taken to quickly sustain stability or clean voltage drop of the power distribution system.

THE INTELLIGENT DETECTION SYSTEM

The intelligent voltage instability detection system comprises two phases. Firstly, the image processing phase; where the PDS voltage output graph images are processed and feature vectors are extracted to be used for training and/or testing the neural network. Secondly, the neural network implementation phase, where the extracted features from the first phase are used as input vectors to a neural network. Our neural network is based on the back propagation learning algorithm due to its implementation simplicity, and the availability of sufficient database for training this supervised learner.

Voltage Output Image Processing

Training and generalizing a neural network using images requires sufficient number of images and meaningful input patterns. Our database contains voltage output images that correspond to a MATLAB-simulated power system. Our concern is with the transient stability of one distribution power substation whose voltage readings are taken as outputs of the circuit after simulation for 20 seconds, which is considered sufficient time to assure the simulation of the three output cases; in particular the overload case. These outputs are graphs of the sinusoidal waves of voltage during the 20 seconds of simulation. For every second on the graph there are 50 full waves, which make them concentrated and appear like a block.

The intelligent voltage instability detection system has three possible output classifications (*Stable*, *Unstable* or *Overload*). The image database has to account for the three cases. For each case there are three voltage output graphs representing three voltage phases (a, b, c). A total number of 54 cases (18 stable, 18 unstable and 18 overload) are simulated, thus resulting in 162 voltage output graph images which form our database. Figure 1 shows examples of the image database representing the voltage output cases (stable, unstable and overload).

The objective of the image processing phase is the extraction of meaningful patterns which form the input to the neural network within the intelligent system. The extracted patterns should distinctly represent the different voltage output cases, while keeping their size to a minimum, in order to reduce the computational cost.

Figure 1. Voltage output image examples

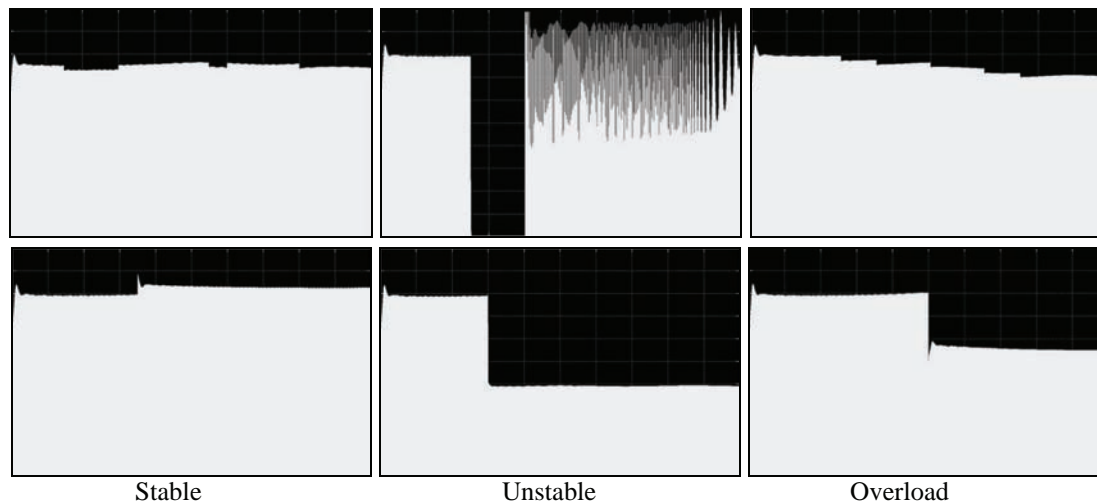

Figure 2 shows an example of finding pixel positions (row numbers) at which the highest voltage value is recorded. The patterns are extracted and saved as a feature vector using the following procedure:

- The three output voltage graphs (representing 3-phase voltage) for every case are saved as digital images with a size of (540x800) pixels.
- Every image is converted to grey and then resized to (202x400) pixels.
- In every image and for every column starting from column 2 to column 201 and from first row to last row, the value of the pixel where the first grey level discontinuity occurs is found and the number of this row is saved in a vector.
- This saved value represents the highest voltage value at that column in that image.
- The process of recording the row numbers where the highest voltage value occurs is repeated for the 200 columns, thus yielding a feature vector with 200 values for each voltage output graph.
- As a result, each case is represented by a pattern or feature vector with 600 values (200 values for each graph. 3 graphs representing 3-phase voltages for each case).

- The number of patterns is equal to the number of cases (54 patterns).
- The 600 values within each pattern are normalized to values from “0” to “1” using division by 400 which is the highest number of rows.
- The normalized patterns are then used as inputs to the neural network classifier for training or generalization.

Neural Network Topology

The second phase in our intelligent detection system is the implementation of the neural network which uses the patterns that were extracted from the voltage output image database. A total of 162 patterns each with 600 normalized values are available for this implementation. Training the neural network uses 30 cases (10 of each: stable, unstable and overload), thus, 90 patterns are used for training the neural network. Testing or generalizing the trained neural network uses the remaining 72 patterns that represent the other 24 cases (8 of each: stable, unstable and overload).

The neural network consists of an input layer with 600 neurons receiving the normalized values in each pattern, one hidden layer with 28 neurons which as-

Table 2. Intelligent voltage instability detection results

| Stable Case | | Unstable Case | | Overload Case | | All Cases | | |
|-----------------|----------------|-----------------|---------------|-----------------|---------------|-----------------|-------------------|--------------------------|
| Training | Testing | Training | Testing | Training | Testing | Training | Testing | Total |
| 10/10 (100%) | 7/8 (87.5%) | 10/10 (100%) | 8/8 (100%) | 10/10 (100%) | 8/8 (100%) | 30/30 (100%) | 23/24 (95.83%) | 53/54 (98.1%) |

asures meaningful training while keeping the time cost to a minimum, and an output layer with 3 neurons representing the voltage output classification of stable, unstable or overload. During the learning phase, the learning coefficient and the momentum rate were adjusted during various experiments in order to achieve the required minimum error value of 0.002 which was considered as sufficient for this application. Figure 3 shows the topology of this neural network and the image pre-processing phase.

Implementation Results

The neural network learnt and converged after 12165 iterations and within 16 minutes (963 seconds), whereas the running time for the generalized neural network after training and using one forward pass was 0.02 seconds. Table 1 lists the final parameters of the successfully trained neural network. Voltage instability detection results using the training image set (90 images representing 30 cases) yielded 100% recognition as would be expected. The intelligent system implementation using the testing image set (72 images representing 24 cases that were not previously exposed to the neural network) yielded correct voltage output classification of 23 cases, thus achieving a 95.83% correct detection rate. Combining testing and training image sets, an overall recognition rate of 98.1% has been achieved. Table 2 shows the intelligent voltage instability detection results in details.

FUTURE TRENDS

The proposed system provides earlier detection of voltage instability. Upon the detection of the instability by the intelligent system, further measures can be taken to quickly sustain stability or clean voltage drop of the power distribution system. Future work will include the development of an intelligent voltage stabilizer that reads the classification output of our proposed intelligent detection system, and performs the necessary measures needed to stabilize the voltage output in case if unstable or overload case detection.

CONCLUSION

A fast and efficient intelligent system for detecting voltage instability in power distribution systems has been developed and presented within this article. Our hypothesis suggested that voltage output images of an assumed power system could be used to train a supervised neural network to classify the status of the power system voltage output.

The neural network within the intelligent system learnt within 963.4 seconds, whereas, the running time for the generalized neural network using one forward pass was 0.02 seconds. The reduction of training and generalization time was achieved by reducing the number of input patterns through processing the voltage output images, and adopting a unique method of extracting the input patterns using pixel positions. Here,

row numbers, at which grey level discontinuities occur, are found for each column in the voltage output graph and recorded for use as input patterns for the neural network implementation.

Our intelligent voltage instability detection system recognized correctly all training patterns as would be expected. Successful results were also obtained when using the testing patterns that were not exposed to the neural network before, yielding 95.83% correct detection. Table 2 showed in details the detection results, where the only incorrect classification of testing patterns occurred with a stable case that was classified as overload case. However, this single incorrect detection is not considered critically dangerous as it would be if, say, an unstable case was mistakenly classified as stable.

Finally, this article has proposed a different approach to detecting voltage instability in PDS by simulating a human operator's monitoring of voltage output graphs. Experimental results suggest that our method performs well and provides a fast and efficient system for voltage instability detection.

KEY TERMS

Artificial Neural Networks (ANN): A network of many simple processors (“units” or “neurons”) that imitates a biological neural network. The units are connected by unidirectional communication channels, which carry numeric data. Neural networks can be trained to find nonlinear relationships in data, and are used in various applications such as robotics, speech recognition, signal processing, medical diagnosis, or power systems.

Back Propagation Algorithm: Learning algorithm of ANNs, based on minimizing the error obtained from the comparison between the outputs that the network gives after the application of a set of network inputs and the outputs it should give (the desired outputs).

Blackout: A power outage (complete collapse), a large-scale disruption in electric power supply.

Iterations: The number of epochs or repetitions of presenting a neural network with training input/output data.

Learning Coefficient: A numerical value that defines the learning capability of a neural network during training.

Momentum Rate: A numerical value that defines the learning speed of a neural network during training.

Pixel: A pixel (short for picture element, using the common abbreviation “pix” for “picture”) is a single point in a graphic image.

Power Distribution System (PDS): Systems that comprise those parts of an electric power system between the sub-transmission system and the consumers’ service switches. It includes distribution substations; primary distribution feeders; distribution transformers; secondary circuits, including the services to the consumer; and appropriate protective and control devices.

SCADA: A system that performs Supervisory Control and Data Acquisition, independent of its size or geographical distribution.

Voltage Instability: Voltage instability analysis is concerned with the inability of assessing the power system to maintain acceptable voltages at all system buses under normal conditions and after being subjected to disturbances (Kundur P. et al., 2004). A major factor contributing to voltage instability is the voltage drop that occurs when active and reactive power flow through inductive reactance of the transmission network. Voltage instability can be caused when a disturbance increases the reactive power demand beyond the sustainable capacity of the available reactive power resources.

Wave Reflection at Submerged Breakwaters

INTRODUCTION

Several types of structures are used in Coastal Engineering with the aim of preventing shoreline erosion, such as groynes, detached breakwaters, submerged breakwaters, etc. Submerged breakwaters have the advantage of their minimal visual impact, which has made them ever more popular (Chang & Liou, 2007).

When the incoming waves impinge on a submerged breakwater, a process of energy transformation occurs. Many laboratory and numerical studies have been carried out in order to investigate this process (Kobayashi & Wurjanto, 1989) (Losada, Losada & Martin, 1995) (Losada, Silva & Losada, 1996) (Liu, Lin, Hsu, Chang, Losada, Vidal & Sakakiyama, 2000). The energy of the incident wave is transformed as follows: (i) one part of this energy is transmitted above the crest of the structure and — in the case of permeable submerged breakwaters — through its interior; (ii) another part is dissipated by wave breaking and by friction with the structure during the transmission process and finally, (iii) the remaining energy is reflected seaward.

The reflection level is related with the scour in front of the structure. Therefore, a good knowledge about the reflection process may be helpful in order to avoid or at least mitigate the possible problems in the structure foundations. However, due to the complexity of the problem, the influence of all the relevant parameters (the structure slope and submergence, the water depth, the wave period and height, etc.) is not entirely understood yet and new approaches are needed.

In this work, an Artificial Neural Network (ANN) has been applied to a series of results obtained from a previous study of Taveira-Pinto (2001), in which several physical models were tested. Once trained and

validated, the ANN has been used to estimate the wave reflection coefficient.

BACKGROUND

ANNs have proved to be a very powerful and versatile Artificial Intelligence technique (Orchad, 1993) (Haykin, 1999). In fact, they have been successfully applied to a great number of areas, including system identification and control, pattern recognition, data processing, time series prediction, modelling, etc (Rabuñal, Dorado, Pazos, Pereira & Rivero, 2004) (Rabuñal & Dorado, 2005).

In Civil Engineering, ANNs have been used most notably in Hydrology (Govindaraju & Rao, 2000) (Maier & Dandy, 2000) (Dawson & Wilby, 2001) (Cigizoglu, 2004). With regard to Ocean Engineering, ANN's have been applied to breakwater stability (Mase, Sakamoto & Sakai, 1995) (Medina, Garrido, Gómez-Martín & Vidal, 2003) (Kim & Park, 2005) (Yagci, Mercan, Cigizoglu & Kabdasli, 2005), wave forecasting (Tsai, Lin, & Shen, 2002) and tide-forecasting (Lee & Jeng, 2002).

ESTIMATION OF THE REFLECTION COEFFICIENT AT SUBMERGED BREAKWATERS

ANN Model

An Artificial Neural Network (Lippmann, 1987) (Haykin, 1999) is an information-processing system

consisting of an interconnected group of many simple process elements. These elements, also called neural units or neurons, work together in a similar way as biological neurons in the brain. The input is presented to the input neurons and propagated through the whole network until eventually some kind of output is produced.

In this work, a FeedForward Backpropagation network (FFBP) has been used. FFBP networks are composed of different layers of neurons linked by means of feedforward connections and trained by a back-propagation algorithm. Feedforward means that the output of a given neuron is used as the input of to the following layer, so there are no feedback loops. In this case, a network with two neuron layers, a logarithmic sigmoid hidden layer and a linear output layer, has been adopted.

The adjustment of the network weights in order to reduce the error is carried out by means of the back-propagation algorithm (Freeman and Skapura, 1991; Johansson et al., 1992). The error, *i.e.*, the difference between the network output and the target (the expected output) is propagated through the network backwards, up to the input layer; all the while the weights are tweaked. This process is repeated over and over until either the error is lower than a threshold or a maximum number of iterations are reached.

The ANN was trained by means of the Bayesian Regularisation method (MacKay, 1992), known to be effective in avoiding overfitting.

Experimental Set Up

The data used for training and testing the ANN were obtained in laboratory tests of submerged breakwaters

(Taveira-Pinto, 2001), carried out in the unidirectional wave tank of the Hydraulics Laboratory of the Faculty of Engineering of the University of Porto. The wave tank is 24.5 m long and 4.8 m wide with a maximum water depth of 0.40 m at the test section. The wave generator is a piston-type paddle, capable of generating regular and irregular waves. At the opposite end, a wave-absorbing gravel “beach” with a slope ratio of 1:20 was used in order to minimize the wave reflection level in the tank.

Six different impermeable models, constructed with wooden panels, were tested with different geometries (Fig. 1) at a 1:100 scale. Model height (h) was equal to 0.20 m in all cases (20 m in prototype). Different slopes (1: n) from 1:1 to 1:5 and two different crest widths (B), 0.05 m and 0.10 m, were tested.

Water surface displacements were measured using twin wire conductivity wave probes placed at different points in the wave tank. In order to evaluate the reflection coefficient (R), three wave probes were located on a line parallel to the wave direction. The spectral analysis method (Gilbert & Thompson, 1978), based on the Kajima (1969) method, was used to separate the incident and the reflection components.

A total of 275 tests were conducted with different water depths and irregular wave conditions. Water depths (d) between 0.20 m to 0.215 m, leading to free-boards (R_c) in the range 0 m to -0.015 m (negative for the breakwater crest below the still water level) were used during the tests. Irregular waves were generated conforming to the JONSWAP spectrum. Significant wave heights (H_s) from 2 cm to 8 cm and peak wave periods (T_p) from 0.8 s to 1.25 s were tested.

In order to carry out the training and the testing process of the ANN, the data were randomly divided

Figure 1. General layout of the testing models

into a training data set (184 tests, or 67%) and a testing data set (91 tests, or 33%)

Both the geometrical parameters of the model and the wave spectrum parameters were introduced as inputs to the ANN by means of the following dimensionless numbers:

- i. $\frac{R_c}{H_s}$ (relative freeboard)
- ii. $k_p B$ (relative crest width)
- iii. $k_p d$ (relative water depth)
- iv. n (slope)

where k_p is the peak wavenumber obtained from the following expression:

$$\frac{4\pi^2}{T_p^2} = gk_p \tanh(k_p d)$$

The output of the ANN is the reflection coefficient R defined as the ratio between the reflected significant wave height and the incident significant wave height.

Training and Testing Process

The MSE obtained in the training and the testing of the ANN was 4.3×10^{-5} and 5.2×10^{-4} respectively. The small value of the testing error proves the ANN ability to generalize the knowledge acquired from the training data.

After the training process, the equation of the best linear fit to the data (Fig. 2) was $y = 0.9967x + 0.0011$, very close to the would-be perfect $y = x$. The value of the correlation coefficient $R^2 = 0.9973$ was also very good.

As was to be expected, the results of the testing process are slightly worse than those corresponding to the training process (Fig. 3). Nevertheless, both the coefficients of the regression equation ($y = 1.0364x - 0.0284$) and the correlation coefficient ($R^2 = 0.9853$) are very good.

ANN Application

Once trained and validated, the ANN was applied to analyze the influence of each input in the reflection process. In Fig. 4, the relative water depth ($k_p d$) is on the abscissa, and the reflection coefficient on the ordinate. Each curve corresponds to a constant freeboard value. The other two inputs were kept constant, the relative crest width at 0.2, and the slope at 1:2.

It means that the more the wave period the less the reflection coefficient in accordance with the experience which states that the long waves are related to higher reflection coefficients than the short waves.

The reflection coefficient decreases as the relative water depth ($k_p d$) increases. As for the relative freeboard, a smaller value (meaning more water over the breakwater crest) leads to a smaller reflection coefficient. In effect, the transmission process becomes

Figure 2. Regression analysis with the training data

Figure 3. Regression analysis with the testing data

Figure 4. Variation of the reflection coefficient with the relative freeboard ($\frac{R_c}{H_s}$)

more efficient with higher submergence levels, leaving less energy for reflection.

The second parameter analyzed was the breakwater slope (Fig. 5). The influence of this input on the reflection coefficient can be easily explained. The limits of the slope value can be linked with a vertical wall ($n \rightarrow 0$) and a horizontal beach ($n \rightarrow \infty$). In the first case, the

reflection is perfect and the reflection coefficient would be equal to 1. In the second, the reflection coefficient goes down to zero as the beach slope tends towards the horizontal. These trends are clearly showed on the graph.

Figure 5. Variation of the reflection coefficient with the breakwater slope (1:n)

FUTURE TRENDS

ANNs have still a long way to go in Ocean Engineering applications. Both the stochastic nature of the wave action and the complexity of the energy transformation processes occurring when waves impinge on a structure lead to very intricate problems, which lend itself very well to ANNs. Hence it is to be hoped that the number of applications increases more and more in the coming years.

CONCLUSION

The estimation of the reflection coefficient at a submerged breakwater under the action of irregular waves is a very difficult task due to the great number of parameters involved: geometry and nature of the structure, water depth, significant wave height, wave period, etc. In this work, the behaviour of submerged breakwaters under the action of irregular waves was analyzed by means of a Feed-Forward Backpropagation network (FFBP), trained and tested on the basis of laboratory tests. The ANN model was shown to fit very closely the results of the physical model tests. The reflection coefficient diminished as the relative water depth increased. The effect of the model geometry is as follows. A decrease in the relative freeboard, meaning a

higher water level over the structure crest, brings about less reflection. As for the seaward slope, the reflection coefficient decreases with it. The curves drawn with resort to the ANN model not only help interpret these trends, but are an useful tool for the design engineer.

KEY TERMS

Artificial Neural Networks: Interconnected set of many simple processing units, commonly called neurons, that use a mathematical model representing an input/output relation.

Back-Propagation Algorithm: Supervised learning technique used by ANNs that iteratively modifies the weights of the connections of the network so the error given by the network after the comparison of the outputs with the desired one decreases.

JONSWAP Spectrum: Wave spectrum typical of growing deep water waves developed from field experi-

Wave Reflection at Submerged Breakwaters

ments and measurements of waves and wave spectra in the Joint North Sea Wave Project.

Peak Period: The wave period determined by the inverse of the frequency at which the wave energy spectrum reaches its maximum.

Reflection: The process by which the energy of the incoming waves is returned seaward.

Significant Wave Height: In wave record analysis, the average height of the highest one-third of a selected number of waves.

Submerged Breakwater: Coastal protection structure crowned at, or below, the still water level.

Web-Based Assessment System Applying Many-Valued Logic

Sylvia Encheva

INTRODUCTION

The issue of rewarding partially correct answers has been addressed by many authors (Guzman, E. & Conejo, R., 2004, Gardner-Medwin, A.R. 1995, Huffman, D, Goldberg, F., & Michlin, M. 2003). Intelligent systems have been designed to assign scores related to the importance of missing or incorrect part of an answer. Such systems are meant to facilitate the process of knowledge assessment. While trying to be efficient in evaluating students' responses these systems operate with the answers to a single question addressing learning a new term, understanding a new concept or mastering a new skill. However, experimental practice shows that asking several questions about the same item results in inconsistent and/or incomplete feedback, i.e. some of the answers are correct while others are partially correct or even incorrect.

A large number of computer based systems and thus automated assessment systems lack the ability to reason with inconsistent information. Such a situation occurs when, f. ex. a student answers to two questions about one item and one of the answers is correct and the other one is incorrect or missing. Reasoning by applying classical logic cannot solve the problem because the presence of contradiction leads to trivialization, i. e. anything follows from 'correct and incorrect' and thus all inconsistencies are treated as equally bad (Priest, 2001).

In this paper we discuss how to assess students' understanding of new terms and concepts, shortly after they have been introduced in a subject. Application of **many-valued logic** allows the system to give meaningful responses in the presence of inconsistencies. Decision making rules, an intelligent agent is applying for assessing students' understanding of new terms and concepts are presented. Such rules distinguish between students' hesitation in the process of giving

an answer and lack of knowledge. We propose use of the generalized **Lukasiewicz's** logic in a Web-based assessment system as a way of resolving problems with inconsistent and/or incomplete input.

BACKGROUND

A brief overview of a six-valued logic, which is a generalized **Kleene's** logic (Kleene, S., 1952), has been first presented by Moussavi, M. & Garcia, N., 1989. Fitting, 1991 developed further this logic by assigning probability estimates to formulas instead of non-classical truth values.

The six-valued logic distinguishes two types of unknown knowledge values - permanently or eternally unknown value and a value representing current lack of knowledge about a state (Garcia, O.N. & Moussavi, M., 1990).

Two kinds of negation, weak and strong negation are discussed in Wagner, G., 1994. Weak negation or negation-as-failure refers to cases when it cannot be proved that a sentence is true. Strong negation or constructable falsity is used when the falsity of a sentence is directly established.

The semantic characterization of a four-valued logic for expressing practical deductive processes is presented by Belnap N.J., 1977. In Gurfinkel, A. & Chechik, M. 2005, it is shown that additional reasoning power can be obtained without sacrificing performance, by building a prototype software model-checker using **Belnap's** logic.

Bi-dimensional systems representing and reasoning with temporal and uncertainty information have appeared also in Felix, P., Fraga, S., Marin, R., & Barro, S., 1999, and Mulstliner, D.J., Durfee, E.H., Shin, K.G., 1993.

A level-based instruction model is proposed by Park, C., & Kim, M., 2003. A model for student knowledge diagnosis through adaptive testing was developed by Guzman, E. & Conejo, R., 2004. An approach for integrating intelligent agents, user models, and automatic content categorization in a virtual environment is presented by Santos, C.T., & Osorio, F.S., 2004.

The Questionmark system at the University of Leeds applies multiple response questions where a set of options are presented following a question stem and the student can select any number and combination of those options. They are significantly more complex than multiple choice questions where the student can select only one among the suggested options. If a student marks some of the correct options (but not all) and or some of incorrect options his/her response can be correct, incorrect, partly correct or partly incorrect. The final outcome is correct or incorrect because the system is based on Boolean logic (Goodstein, R. L., 2007).

MAIN FOCUS OF THE CHAPTER

The test consists of two questions. According to the result of a test, understanding of a term or concept is achieved if a student gives a correct answer to questions about that term or concept. Such tests are placed after a new term or concept has been introduced in the theoretical part of a tutoring system. Questions in such tests should provide information about

- the student's knowledge,
- the subtler qualities of discrimination, judgement, and reasoning necessary in scientific reasoning,
- evaluate the student's judgement as to whether cause and effect relationships exist, and student's comprehension of a described situation.

Understanding of a Term

For evaluating understanding of a single term we propose a test where the choices can result in a correct answer, incorrect answer or unanswered question.

- Two correct answers imply understanding of that particular term. The process of questioning is terminated.
- One correct answer and one unanswered question imply some doubt about the student's understand-

ing of that particular term. The system first provides additional explanations and then suggests to the student to answer one new question taken from the database.

- One correct answer and one incorrect answer imply doubt about the student's understanding of that particular term. The system first provides additional explanations and then suggests to the student to answer two questions where one new question is taken from the database and the other question is taken from the first trial and has received an incorrect answer.
- Two unanswered questions imply uncertainty about the student's understanding of that particular term. The system first provides additional explanations and then suggests two new questions taken from the database.
- One incorrect answer and one unanswered question imply doubt about the student's understanding of that particular term. The system first provides additional explanations and then suggests to the student to answer the same questions.
- Two incorrect answers imply lack of understanding of that particular term. The system first provides additional explanations and then suggests to the student to answer the same questions plus one new question taken from the database.

If the second set of responses contains an incorrect answer and/or unanswered questions the system advises the student to work more with the originally provided learning materials and terminates the automated questioning process. We believe that several rounds of questioning would make the learning process time consuming for the student and thus disturb the learning flow.

However, the student can start a new assessment of his/her understanding of that particular term at any time he/she wants.

Understanding of a Concept

For evaluating understanding of a concept we propose a test with two questions where the choices can result in correct answer, partially correct answer, wrong answer or unanswered question.

- Two correct answers imply understanding of the concept. The process of questioning is terminated.
- One correct answer and one partially correct answer imply doubt about the student's understanding of the concept. The system first provides additional explanations and then suggests to the student to answer to the same question that has received a partially correct answer.
- One correct answer and one unanswered question imply doubt about the student's understanding of the concept. The system first provides additional explanations and then suggests to the student to answer one new question taken from the database.
- One correct answer and one wrong answer imply some doubt about the student's understanding of the concept. The system first provides additional explanations and examples, and then suggests to the student to answer again to the question that has previously received a wrong answer and one new question taken from the database.
- Two partially correct answers imply doubt about the student's understanding of the concept. The system first provides additional explanations selected theory and examples, and then suggests to the student to answer to the same questions.
- One partially correct answer and one unanswered question imply doubt about the student's understanding of the concept. The system first provides additional explanations and then suggests to the student to answer two new questions taken from the database.
- One partially correct answer and one wrong answer imply doubt about the student's understanding of the concept. The system first provides additional explanations, selected theory and examples, and then suggests to the student to answer two new questions taken from the database.
- One wrong answer and one unanswered question imply doubt about the student's understanding of the concept. The system first provides additional explanations selected theory and examples, and then suggests to the student to answer to the question that has previously received a wrong answer and a new question taken from the database.

Tests with a Larger Number of Questions

A test with three questions where the possible responses are correct answer, incorrect answer and a partially correct answer would require fifteen-valued logic. The generalized **Lukasiewicz's** logic provides a solution for a test with any number of questions and answer options.

System Architecture

The system implementation is using the so-called **LAMP** Web server infrastructure and deployment paradigm. It is a combination of free software tools of an Apache Web server, a database server and a scripting programming platform on a Linux operating environment.

Behind this traditional three-tiers Web deployment is a service support sub-system. Communication framework based on **XML-RPC** is used to connect the Web application middle-ware and the intelligent assessment/diagnostic system together. The separation of these two units made it possible to modularly design and implement the system as loosely couple independent sub-systems.

The dynamic page publisher compiles a page to be presented to the user from a template file in relation to the user response, current state variables and activities history. A template file contains the static declarations of a document. The variables in a particular template files are given values by the dynamic page publisher module during the production of an HTML document. The resulting HTML document is sent back to the user Web browser. This module also acts as a handler when a user requests a page or sends a form back to the Web server.

The users stack profiler keeps track of user activities history in a stack like data structure in the database. Each event, like for example response/result of a test or a change of learning flow after following a hint given by the system, is stored in the database. This module provides the percept to the intelligent modules of the software agents' sub-system. The users stack profiler communicates directly with the agents by sending messages over the **XML-RPC** communication channel. By using some common data stored in the database, the users stack profiler indirectly affects the behaviour of the user's agents and visa verse.

The application middleware and the software agents run independently of each other. As such, they can be situated on different servers. The middleware implement the Web side of the system while the software agents implement the decision side of users learning process. Given a certain response to a particular test at a particular user state, what best action can be taken to increase the probability that the user will learn a particular unit of knowledge? This decision is done by the intelligent diagnostics agent.

The intelligent assessment agent does an early diagnostic about absorption of knowledge. A response given by a particular student from a test will give the system an indication about the state of learning of a particular term. This agent helps to implement a part of an intelligent tutoring system, which differ from the intelligent diagnostics agent. The intelligent assessment agent facilitates students' early absorption/assimilation of new terms.

FUTURE TRENDS

The proposed assessment system is based on many-valued logic. Further research is needed to investigate which of the available non-classical logics can provide more accurate assessments according to what is the subject of that assessment - knowledge of a term, understanding of a concept, level of mastered skill, etc.

Another important area for future work involves recommendation, of hints, explanations, examples, and theory, tailored to each student's responses and needs.

CONCLUSION

This paper is devoted to assessing students understanding of new terms and concepts. The presented framework provides flexibility in the choice of logic and can serve as an effective exploration tool for reasoning about many combinations of input coming from different sources.

KEY TERMS

Belnap's Logic: It has four truth values 'T, F, Both, None'. The meaning of these values can be described as follows: an atomic sentence is stated to be true only (T), an atomic sentence is stated to be false only (F), an atomic sentence is stated to be both true and false, for instance, by different sources, or in different points of time (Both), and an atomic sentences status is unknown. That is, neither true, nor false (None).

Kleene's Logic: Kleene's logic has three truth values, truth, unknown and false, where unknown indicates a state of partial vagueness. These truth values represent the states of a world that does not change.

LAMP Web Server: It is a combination of free software tools of an Apache Web server, a database server and a scripting programming platform on a Linux operating environment.

Lukasiewicz's Three-Valued Logic: Lukasiewicz's three-valued logic has a third value, $1/2$, attached to propositions referring to future contingencies. The third truth value can be construed as 'intermediate' or 'neutral' or 'indeterminate'.

Lukasiewicz's Generalized Logic: It is done by inserting evenly spaced division points in the interval between 0 and 1.

Six-Valued Logic: The six-valued logic obtained as an extension of the Kleene's logic has six truth values - *true*, *false*, *unknown*, *unknown_t* - intermediate level of truth between *unknown* and *true*, *unknown_f* - intermediate level of truth between *unknown* and *false*, *contradiction*.

XML-RPC: It is remote procedure calling using HTTP as the transport and XML as the encoding.

Workflow Management Based on Mobile Agent Technology

Marina Flores-Badillo

CINVESTAV Unidad Guadalajara, Mexico

Ernesto López-Mellado

CINVESTAV Unidad Guadalajara, Mexico

INTRODUCTION

Nowadays Information Systems (IS) are designed for individual task execution control allowing coordinating, monitoring, and supporting the logistical aspects of a *business process*, in other words, the IS has to manage the flow of work through the organization.

The WorkFlow Management represents a critical issue for achieving enterprise competitiveness among organizations. Many companies have realized that the *business processes (BP)* within their organizations, and between the companies and their partners have not been clearly described and there are not enough techniques and methods to automate the processes.

The *Workflow Management Coalition (WFMC)* states that *workflow (WF)* is concerned with the automation of procedures where documents, information, or tasks are passed to the participants according to a defined set of rules to achieve, or contribute to, an overall business goal (WfMC, 1999). Another definition of WF can be found in (Rusinkiewicz & Seth, 1994) where *workflows* are *activities* involving the coordinated execution of multiple tasks performed by different processing entities (persons or machines). A *task* or process involves a piece of work and a process entity which executes the work.

Workflow Management (WFM) is a fast evolving technology which is increasingly being exploited by businesses in a variety of industries. Its primary characteristic is the automation of processes involving combinations of human and machine-based activities (Aalst & Hee, 2002), (Aalst, 1998).

A *Workflow Management System (WFMS)* provides procedural automation of a *business process* by management of the sequence of work activities and the invocation of appropriate human and/or IT resources associated with the various activity steps. Although the most prevalent use of *WFMS* is within the office

environment in staff intensive operations such as insurance, banking, legal and general administrations, etc, it is also applicable to some classes of industrial and manufacturing applications (WfMC, 1995). *WFMS* needs to integrate other technologies such that *agent* technology, which provides flexible, distributed, and intelligent solutions for business process management.

This work presents a methodology for mobile agent-based WFMS development. The proposed methodology consists of a modular and gradual specification of the system where a mobile agent guides the process through organizational units and executes different tasks. Several mobile agents evolve through the system executing concurrently their assigned task.

BACKGROUND

Workflow Management

The notion of *agent* in (Yuhong, Zakaria & Weiming, 2001) is used as “a computer system situated in some environment, which is capable of autonomous action in this environment in order to meet its design objectives” (different notions can be found in (Wooldridge, 2002) and (Nwana, 1996)). These works also highlight the benefits of applying agent technology to *business process* management; some of these benefits are: distributed system architecture, the inherent autonomy of software agents because agents can start a WF based on event trigger, the agent reactivity because it have the ability to generate alternative execution paths, etc. An intelligent agent is capable of autonomous operation and flexible behavior in order to meet its design goals and also has the properties of reactivity, pro-activity, and social ability (Wooldridge, 2001).

In other works both concepts are integrated. In (Repetto, Paolucci & Boccalette, 2003), a methodol-

ogy for the design of agent based WF was presented; it consisted in three steps. In the first step the authors model the *BP* with UML Activity diagrams by identifying all the necessary resources and activities. In the second step, all the activities identifying roles in parallel paths are grouped. Finally, they define an agent for each group.

Several researchers took the *agent* technology for the improvement of WF applications. In (Marin & Brena, 2005), an architecture for high-level agent-based WF is proposed. On this architecture they break down the WF execution and the process flow control in small execution units handled by intelligent agents and a WF processes is controlled in a decentralized way.

A collaborative approach for workflow systems is presented in (Savarimuthu & Purvis, 2004) where agents collaborate by forming social network (societies), in (Savarimuthu, Purvis & Fleurke, 2004) agents are embedded in a system that can monitor and control the overall functioning of a workflow process in an agent based WF system.

In (Minhong, Huaquing & Dongming, 2005), agent technology is used for the WF monitoring where various intelligent agents working together to perform flexible monitoring tasks in an autonomous and collaborative way.

Multi-Agent Systems

Mobile agents are autonomous programs that can travel from one computer to another under its own control. They offer a robust and efficient framework to develop distributed applications including mobile applications.

A stationary agent is executed only on the system where it began its execution. If it requires information from a different system or needs to interact with another agent, it uses a standard client-server communication (RMI, RPC, CORBA).

A mobile agent (MA) is not always attached within the systems where it starts the execution, rather it is capable of moving itself through the network nodes where it is allowed, modifying eventually its execution environment; the MA carries with itself its current state and its code (strong mobility). Furthermore, MAs may exhibit several advantageous features due to mobility, for example a) interaction with the resource during its migration to the needed resource location, keeping the bandwidth and reducing the latency of the network

(Cabri, Leonardi & Zambonelli, 1998), b) interaction with the users during the migration to the user location, answering faster user requests. In both cases the agent continues the interaction with the resource or the user even with temporary network connections failures.

Most of distributed applications fit naturally on the model of MAs because the agents can migrate sequentially through a computer network, they send other agents to visit computers in a parallel way, they remain stationary and interact with remote resources, etc.

There exist several organizations with the aim of establishing standards for agent software development and agent interoperability. One of them is FIPA (FIPA, 1997).

JADE Development Tool

JADE (Java Agent Development Framework) is a software framework completely implemented in Java language which simplifies MA system implementations by using a middleware which fulfill FIPA (FIPA, 1997) specifications. The agent platform can be distributed through machines (which not necessary share the same OS) and the configuration can be managed by a remote GUI (Bellifemine, Caire, Trucco & Rimassa, 2006).

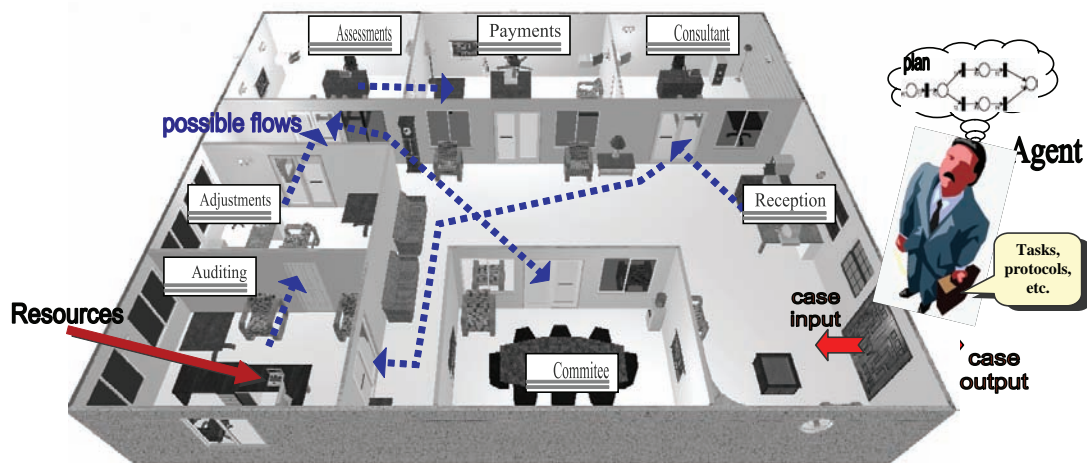

The communication architecture offers flexible and efficient message passing where JADE creates and manage the incoming private ACL message queue for each agent. The complete FIPA communication model has been implemented and its components have been clearly distinguished. JADE integrates completely interaction protocols, ACL, ontology's, transport protocols, etc. Most of the FIPA defined protocols are available in JADE.

MOBILE AGENT-BASED WFMS DEFINITION

This work presents a methodology for the development of Mobile Agent-based *WFMS*. The basic idea for conceiving such a system is that a MA guides the workflow process through the different organizational units in which several *tasks* are executed according to the handled *case*.

During the design phase the components are described in a clear and compact way. The system is described as a set of interconnected organizational units that have a specific resource allocation. The agent

Figure 1. Structuring the design of a WfMS

behavior is determined by two kinds of specifications: a) the description of the agent general behavior and common knowledge for all the agents, namely, basic operations, and interaction protocols (collaboration, and resource competition); and b) particular descriptions of a specific behavior such as the *task* plan and an accessibility roadmap, which describe the assigned process and the permitted access to the organizational units respectively. This strategy is illustrated in figure 1.

The implementation phase is supported by a software development guideline allowing the definition of Java components (using also the middleware JADE) from agent systems specification from the design phase. The obtained software is distributed in a set of networked computers that manages MA migration. The modularity allows adaptations to system specification changes without difficulties.

For the sake of readability the proposed method is illustrated through a case study dealing with claim processes in an insurance company.

Case Study Description

The problem can be defined as follows: “*Define the WF for the claim processes in an insurance company in which a customer claims the insurance policy of a personal property (real state, car, life insurance). The company must receive the claim, request personal data from the customer (insurance policy number, etc.), and validate the insurance validity, payments and beneficiaries. It must do the adjustment of real damages, validate the case, calculate the correspondent assess-*

ment, do the necessary payments to the customer if the complain is valid, or inform in case that the process has some invalid data”

Design Methodology

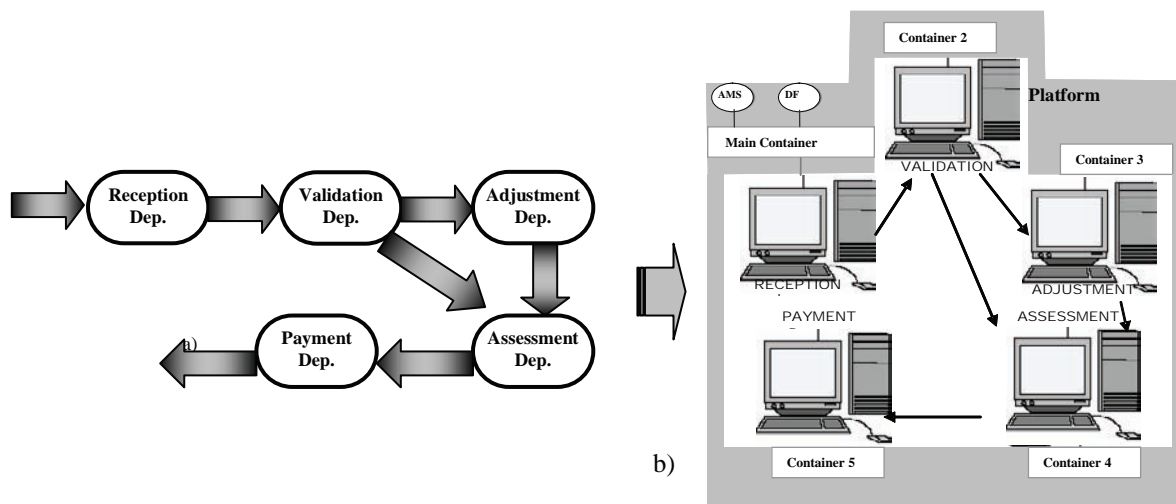

The MA that guides the process through the company must have the previous knowledge of organizational units allocation, resource allocation, the execution plan, the list of *tasks* to perform and, the different needed protocols for the resource solicitation or competition. Additionally the MA must know the environment structure, which is first specified.

Environment specification. The agent environment is defined by the diagram that represents the general structure of the company. It is necessary to identify the different departments in which some task is executed or the information flows, considering all the possible *cases*. Then each department or office is represented by a JADE agent container where we can suppose that each container is on a different host of a distributed network system. In this way each department is represented by a host. A host can belong to different platforms, but for simplicity work we suppose that all hosts belong to the same platform.

Here we propose a strategy for the platform definition but this can have a different distribution. So, for the platform distribution it is important to:

- Identify the departments involved with the process considering all the possible *cases*.

Figure 2. Claim insurance process a) Block diagram of the organizational units b) Environment Definition

- Identify the information flow and its direction.
- Construct a block diagram with the obtained information.

In this diagram, each block represents a site or host of a distributed system (each host has a JADE agent container) and the arrows represent the direction of the flow or a possible agent migration.

Consider that in our case of study there are five departments: reception, validation, assessment, adjustment and payment; we can get the blocks diagram and the possible platform configurations as the figure 2.

In JADE the containers creation is achieved as follows:

- Main Container, on commands line of the site that are going to have this particular kind of container we can write:

```
C:\ java JADE.Boot -container-name Name_Host [-gui]
```

where each [] represents an optional parameter.

- The rest of the containers are created using the line:

```
C:\ java JADE.Boot -container-name Name_Host -container -host HostMainContainer
```

- We can also use the GUI of JADE for the creation of containers and agents

Mobile Agent Definition. For the case study, the states of the agent general behavior can be easily represented for the Petri net showed in fig. 3. The MA selects a plan execution according to the *WF process definition* for the assigned case; the plan indicates which sites the agent must visit in order to process the case, an access map for the sites, information for resource reservation. Also the agent migrates from one site to another, collaborates with other agents, competes for resource allocation, etc.

In JADE a mobile agent is created as a sub-class of the generic class *Agent* and its service is registered with the DF of JADE. We can use the code in Exhibit A.

The particular behavior for this agent is given for the WF process definition. In other words, is defined for the order execution of the tasks involved in the process of the case. For the programming of the plan we can use the available Behaviours of JADE because they represent the tasks that an agent can perform. We can use any of the different behaviours included in JADE according to the plan to perform.

The plan is obtained from the *WF process definition*; it defines the execution sequence of the involved tasks; so, sometimes it is necessary to construct a diagram (like a flow diagram) specifying sequence when it includes

Exhibit A.

```

public class MobileAgent extends Agent {
protected void setup() {
DFAgentDescription dfd = new DFAgentDescription();
dfd.setName(getAID());
ServiceDescription sd = new ServiceDescription();
sd.setType(Type);
sd.setName(Name);
dfd.addServices(sd);
try {
DFService.register(this, dfd);
} catch (FIPAException fe) { fe.printStackTrace(); }
} }

```

Figure 3. Petri Net for the Agent general behavior

alternatives; the diagram must indicate in which department the task must be performed or executed.

Following the case study, assume that the obtained diagram is that shown in figure 4; in this figure both the task name and the corresponding department are indicated.

If the execution sequence of tasks follows the behavior of a Finite State Machine (FSM) we use the JADE FSMBehaviour.

```

FSMBehaviour fsm = new FSMBehaviour(this) {
public int onEnd() {
System.out.println("FSM behaviour completed");
myAgent.doDelete();
return super.onEnd(); } };

```

If we use this particular behavior we have to register the appropriated states which represent each task to perform, and the transitions that represent its sequence or its execution order. In this way, for the register of states it is used the function:

```
registerState(Function_Name_Task, state_name);
```

where the first parameter indicates the name of a function for the correspondent task and the second parameter indicates a name for this state used for the transitions registration.

For this we use the function:

```
RegisterDefaultTransition(state_name1, state_name2),
```

which indicates that after the complete execution of the function represented for the state *state_name1* the function for the state *state_name2* is performed.

Some states and transitions for the case study could be those showed in figure 4. Also one must add other states (*MovValBehaviour*, *MovValoBehaviour*, *MovCo-tizBehaviour* y *MovPayBehaviour*) for the migration of the agent when the performed task must be realized in a department different to the current.

Because of the agent migration the appropriated mobility ontology must be registered:

```
getContentManager().registerLanguage(new SLCodec(), FIPAN-
ames.ContentLanguage.FIPA_SL0);
// register the mobility ontology
getContentManager().registerOntology(MobilityOntology.get-
Instance());
```

When the states for the *FSMBehaviour* are registered we use only a name for the function to perform; so, it is necessary to add the Java statements for each function for the selected behavior. Each one of these methods is added as a class that inherits of one of the *JADE Behaviours*. These methods contain the statements to execute in each task; for the case study a method definition is included in figure 4.

If the agent has to collaborate with another agent to perform a task, the JADE protocol FIPA-Request can be used (an example is shown in figure 5).

Following the guidelines given above the general behavior of the MA and the environment where it evolves can be defined. In a similar way the behavior of stationary agents can be also established.

The proposed methodology has been applied to several case studies leading to modular software, which has been executed on several networked (LAN) personal computers. The tests were performed on sites in which a JADE platform was defined. Nevertheless different configuration platforms can be integrated in the WFMS.

FUTURE TRENDS

The proposed methodology for the development of WFMS is a first step towards the automation of complex business processes in large enterprises. However in companies where the organizational units are distributed

in several cities, the MA must travel though the web; then more sophisticated capabilities must be added to the agents and their environment, namely security protocols and agent losses control.

Furthermore, it would be advantageous consider the interaction with existing WFMS based on the standards provided by WPMC to profit of existing information and business strategies.

CONCLUSION

Automation of business processes yields improvements to the productivity of companies. This work proposed a methodology for developing WFMS based on mobile agent technology. This methodology allows modular definitions for the environment and mobile agent behaviors. The proposed implementation technique uses JADE getting all the JAVA advantages. The mobile agent can interact with other agents to collaborate, negotiate or compete for resources. Due to the modularity of the obtained software, it can be easily modified according to modifications to WFMS specifications.

KEY TERMS

Activity: A description of a piece of work that forms one logical step within a process. An activity may be a manual activity, which does not support computer automation, or a workflow (automated) activity.

Agent: An agent is a computer system situated in some environment, and that is capable of autonomous action in this environment in order to meet its design objectives.

Business Process: A set of one or more linked procedures or activities which collectively realize a business objective or policy goal, normally within the context of an organizational structure defining functional roles and relationships.

Case: The representation of a single enactment of a process, using its own process instance data, and which is (normally) capable of independent control and audit as it progresses towards completion or termination.

Mobile Agent: A program that can migrate from a computer to other computer within a heterogeneous network. The program chooses when and where to migrate. It can suspend its execution at an arbitrary point, transport to another computer and resume execution in the new computer.

Multi-Agent System: Is a collection of software agents that work in conjunction with each other. They may cooperate or they may compete, or some combination of cooperation and competition.

Process: A formalized view of a business process, represented as a co-coordinated (parallel and/or serial) set of process activities that are connected in order to achieve a common goal.

Process Definition: The representation of a business process in a form which supports automated manipulation, such as modeling, or enactment by a workflow management system.

Workflow: The automation of a business process, in whole or part, during which documents, information or tasks are passed from one participant to another for action, according to a set of procedural rules.

Workflow Management Coalition: The WFMC is a non profit organization with the objectives of advancing the opportunities for the exploitation of workflow technology through the development of common terminology and standards.

Workflow Management System: A system that completely defines creates and manages the execution of workflows through the use of software, running on one or more workflow engines, which is able to interpret the process definition, interact with workflow participants and, where required, invoke the use of IT tools and applications.

 - evolutionary computation (EC) techniques 647
 - evolutionary computation, definition 493, 580, 602, 624, 807, 859, 872, 1144, 1309
 - evolutionary computing 10
 - evolutionary grammatical inference 596
 - evolutionary learning algorithms 1014
 - evolutionary mechanism, definition 1302
 - evolutionary optimisation 1042
 - evolutionary optimization method 522

evolutionary programming, definition 1144
 evolutionary robotics 603, 604, 608, 1101
 evolutionary techniques 588, 648, 653
 evolutionary techniques, variable selection 581
 evolutionary time, definition 574
 evolvable hardware 614, 616
 evolved synthesis of digital circuits 609
 exclusion error 1357
 executive information systems 1310
 expansion operator 600
 expansion, definition 1374
 expectation, definition 1184
 expected value, definition 436
 expert combination 318
 expert knowledge, definition 336
 expert systems 1404
 expert systems, commonsense 334
 explanatory variables, definition 423
 exploitation, definition 1196
 exploration, definition 1196
 exploratory data analysis, definition 787
 extended Kalman filter 1417
 extension aware techniques, definition 500
 extensivity, definition 1110
 external memory breadth-first search 502
 external memory heuristic search 503
 external memory search algorithms 502

F

F1-measure, definition 545
 face detection, definition 1265
 face identification, definition 1265
 face recognition 248, 1455–1461
 face recognition, definition 371
 facial expression recognition 625
 facial expression recognition system, definition 630
 fact table, definition 430
 factor analysis, definition 901
 factored-state Markov decision process, definition 830
 factors, definition 1574
 fan-in, definition 479

fast correlated-based filter (FCBF) method 634
 fault-tolerant, definition 479
 feature extraction 202, 1449
 feature extraction problem, definition 1190
 feature extraction, definition 1454
 feature extraction, definition 371, 638
 feature selection 66, 632
 feature selection, definition 371, 559, 638
 feature selection, definition 916, 1237
 feature space, definition 560
 feed forward off-chip implementation 834
 feed-forward artificial neural network 639–646
 feed-forward artificial neural network, definition 1011, 1017
 feed-forward artificial neural networks 1004, 1012
 feedforward neural networks, definition 1395
 field programmable array (FPGA), definition 560
 field programmable gate array (FPGA) 555
 filling factor, definition 1302
 filter method, definition 638
 finite automata, definition 602
 finite element method, definition 553
 FIPA, definition 923
 first-order method, definition 1011
 first-order predicate calculus 334
 FIS, definition 1242
 Fischertechnik system 1385
 fitness function 756, 1303
 fitness function, definition 595
 fitness function, definition 758, 872, 1309
 fitness landscape, definition 1150, 1196
 fitness, definition 773, 1150, 1196
 fixed point theorem, definition 1224
 fixed search 584
 flexible manufacturing system (FMS) 749
 flexible query, definition 931
 flocking, definition 540
 Floreano, Dario 605
 FOCUS 634
 fonator system 1439, 1445

forward chaining, definition 995
 forward selection strategy, definition 545
 forward selection, definition 882
 Foundation for Intelligent Physical Agents 1405
 Fourier transform (FT) 223
 FPGA implementation of ANNs 831
 FPGA, definition 839
 frames 329
 Fraunhofer AIS, Germany 1385
 frequency domain stability inequality of Popov, definition 1224
 frequent item-sets, discovery of 77
 frequent item-sets, generating 77
 FTS engine interface 657
 FTS engine, structure of 656
 full adder, definition 1480, 1561
 full factorial design, definition 1574
 full-text search 656
 full-text search (FTS) engine, definition 660
 full-text search engines 654
 functional data analysis, definition 666
 functional dimension reduction 661
 functional equation, definition 676
 functional imaging 372
 functional network, definition 676
 functional networks 667
 fusing variables, definition 1517
 fusing variables, definition 462
 fuzzification 970
 fuzzification, definition 695, 718, 766, 973, 1128
 fuzzy algorithm, definition 718
 fuzzy approximation of DES state 677
 fuzzy ART equations 1492
 fuzzy ART neural network stream processing 1491
 fuzzy ART training process 1492
 fuzzy ART, definition 1496
 Fuzzy ART, definition 1503
 fuzzy clustering algorithms 711
 fuzzy c-means (FCM) 711
 fuzzy compositional rule of inference (CRI), definition 733
 fuzzy control, definition 695
 fuzzy decision trees 696
 fuzzy inference system 1124
 fuzzy inference systems, definition 718, 823

fuzzy k-nearest neighbour (FKNN) 711
 fuzzy logic 31, 330, 710, 797, 884
 fuzzy logic estimator 719
 fuzzy logic in data mining tasks 884
 fuzzy logic systems, supervised learning of 1510
 fuzzy logic, definition 462, 687, 695, 727, 802, 816, 891, 973, 1128, 1237, 1496, 1517
 fuzzy matching, definition 660
 fuzzy membership function, definition 695
 fuzzy neural networks (FNN) 32
 fuzzy operator, definition 718
 fuzzy petri nets, definition 687
 fuzzy relational neural network (FRNN), definition 866
 fuzzy rule base, definition 462, 1517
 fuzzy rule interpolation 728
 fuzzy rule interpolation methods 729
 fuzzy rule interpolation, definition 733
 fuzzy rule, definition 742, 1128
 fuzzy set theory, definition 780
 fuzzy set, definition 695, 708, 802, 973
 fuzzy similarity calculation 800
 fuzzy similarity for data classification 796
 fuzzy similarity representation 798
 fuzzy similarity representation, model for 798
 fuzzy SQL query, definition 932
 fuzzy SQL, definition 931
 fuzzy system (FS), definition 766
 fuzzy system, definition 695, 742, 1129, 1403
 Fuzzy systems 884
 fuzzy systems, multilayer optimization approach for 1121
 fuzzyfication, definition 727

G

game-based learning 140
 games theory, definition 1023
 gas-fired cooktop burners 1568
 gas-fired cooktop burners, thermal design 1568
 gate (logic), definition 479
 Gaussian distribution, definition 1087
 Gazetteer, definition 1567
 gene expression 236, 241

gene expression data, cluster analysis 289–296
 gene expression, definition 1211
 gene finding 237
 gene mapping 242
 gene regulation network use 744–747
 gene regulatory network 237
 gene, definition 382, 1595
 generality 334
 generalization, definition 1523
 generalized cellular automaton, definition 359
 generalized constraint language 777
 generalized constraints 777
 generalized cylinder (GC) 114
 generalized theory of uncertainty (GTU), definition 780
 generalized-regression (GR) NN, definition 1424
 generation, definition 1150, 1196
 generative topographic mapping (GTM), definition 795
 generic gate 614
 genes, definition 595
 genetic algorithm 592, 653, 742, 766, 807, 916, 1101, 1302, 1335, 1488
 genetic algorithm, with division into species 651
 genetic algorithms (GA), definition 616
 genetic algorithms (GAs) 647, 748–754, 1504
 genetic algorithms components, definition 1517
 genetic algorithms components, definition 462
 genetic algorithms, definition 758, 859, 872, 1237
 genetic fuzzy rule generator architecture 457
 genetic fuzzy system 762
 genetic fuzzy system, definition 766
 genetic fuzzy systems, ports and coasts engineering 759
 genetic networks 242
 genetic operators 599
 genetic operators 762
 genetic operators, performance effect of 1504–1509
 genetic pool 650
 genetic programming (GP) 241, 527, 598, 619

genetic programming, definition 773, 916
 genetic regulatory network model 745
 genome encoding 762
 genotype, definition 617, 624
 geodesic active contour model 549
 geodesic curve, definition 553
 geriatric residences, planning agent for 1316–1322
 GGGP systems, crossover operator 769
 Gibbs sampler, definition 1465
 global classification 1359
 global constraint, definition 409
 global path planner, definition 1079
 global path planners 1072
 global stability, definition 1224
 GNG, definition 1218
 gold-silver price, definition 1003
 GP 590
 GPGPU (general-purpose computation on GPUs), definition 1496, 1503
 GPU (graphics processing unit), definition 1496, 1503
 gradient descent 1417
 grammar evaluation 600
 grammar genetic programming approach 599
 grammar-guided genetic programming (GGGP) 767
 grammar-guided genetic programming, definition 773
 granular computing 774, 775
 granular computing, definition 780
 granulometries 1107
 graph edge, definition 1079
 graph invariant, definition 709
 graph node, definition 1079
 graph partition problem 1115
 graph subsumption, definition 1184
 graph, definition 505
 graph, definition 709
 graphics processing units (GPUs) 873–878
 greedy algorithm, definition 546
 greedy search, definition 883
 gross errors, definition 1395
 growing cell structures 782
 growing cell structures visualization 781
 growing cell structures, definition 787

growing neural gas (GNG) 1364
 growing neural gas, definition 1368
 GTM user modeling 788

H

HAM-PHAM 828
 hardware genetic algorithm (HGA) 612
 harmony search (HS) 803
 harmony search model and application 803
 harmony search, definition 807
 Harris corner detector, definition 389
 HCI applications 625
 health care agent, nature-inspired 1317
 Hebbian learning, definition 1368
 heterogeneous multi-core computing, definition 1503
 heuristic function, definition 506
 heuristic information, definition 1535
 heuristic knowledge, definition 995
 heuristic modelling 968
 heuristic, definition 486, 602, 1023, 1465
 HEXQ 828
 HGA, definition 617
 Hidden Markov Model 1565
 Hidden Markov Model (HMM), definition 630, 1567
 hierarchical fuzzy logic systems 456
 hierarchical fuzzy logic systems, definition 463, 1517
 hierarchical neuro-fuzzy systems 808, 817
 hierarchical reinforcement learning 825, 830
 hierarchical task decomposition, definition 830
 high level synthesis, definition 839
 holographic reduced representation (HRR), definition 519
 holonomous robot, definition 847
 homogeneous multi-core computing, definition 1503
 HOPS 840, 841
 HOS 1226
 HOS, definition 1231, 1272
 Human Genome Project 236
 human-computer interaction (HCI), definition 631
 human-machine interaction 628
 hybrid algorithm 636
 hybrid dual camera systems 849

hybrid dual camera vision system 840
 hybrid intelligent system, definition 866, 872
 hybrid intelligent systems 854
 hybrid intelligent systems, definition 859
 hybrid meta-heuristics based scheduling system 855
 hybrid method, definition 638
 hybrid methods 636
 hybrid methods, definition 1079
 hybrid navigation 1076
 hybrid omnidirectional pin-hole sensor (HOPS) 841
 hybrid perspective 1589
 hybrid scheduling module 856
 hybrid space, definition 1595
 hybrid spaces 1589
 hybrid two-population genetic algorithm 585, 649
 hybridization, definition 780
 hypergraph, definition 709

I

ICA model 22–30
 idempotence, definition 1110
 IFIP framework 968
 IF-THEN rules, definition 727
 ill-posedness, definition 375
 image - video face recognition 1457
 image analysis, definition 1309
 image analysis, particle swarm optimization 1303
 image integration 373
 image integration, definition 376
 image moments, definition 389
 image pre-processing 1448
 image pre-processing, definition 1454
 image processing, definition 973
 image rectification 384
 image restoration, and Bayesian neural networks 223–230
 image segmentation 373
 image transformation, definition 1110
 image-based visual homing 1185, 1190
 immersive technologies 536
 immune artificial system 238
 impact-echo 192–198, 199–205
 implementation, definition 336
 implicit hybridization 1194
 imprecise marking, definition 687
 inclusion error 1357
 increasingness, definition 1111
 incremental learning operator 600
 independence assumption 880
 independence subspaces, definition 901
 independent component analysis (ICA) 270–274, 883, 1265
 independent subspaces 892
 indexer, definition 660
 individual, definition 493, 574
 induction, definition 703
 infant vision system 248
 inference network, definition 995
 inflective language, definition 1472
 inflective languages, statistical modelling of 1467
 information extraction (IE) 106, 1567
 information pattern, definition 1218
 information potentials and forces, definition 909
 information processing, definition 342
 information quality decay, definition 423
 information retrieval, and AI 151–156
 information retrieval, definition 423
 information theoretic learning (ITL) 902
 information theoretic learning, definition 909
 initial annealing temperature, definition 574
 initial population 592
 input data selection 578
 insect behaviour 1537
 instance, definition 891
 institutional memory, definition 988
 intelligence, definition 939
 intelligent agent, definition 51, 431, 535, 932, 1431
 intelligent MAS 917
 intelligent query answering mechanism 924
 intelligent radar detectors 933, 934, 935
 intelligent software agent, and e-commerce 941–944
 intelligent software agent, definition 955

intelligent software agents 951
 intelligent software agents, and e-commerce 945–949
 intelligent software agents, applications in focus 950
 intelligent system 51
 intelligent systems 257
 intelligent traffic sign classifiers 956
 intelligent tutoring system (ITS), definition 1257
 intelligent tutoring system, definition 1184
 intelligent tutoring systems 138
 intelligent tutoring systems, NLP techniques in 1253
 intelligent voltage instability detection system 1597
 Intellimetric 139
 intension aware techniques, definition 500
 interactive configuration 401
 interactive systems, and uncertainty 963–966
 interactive systems, managing uncertainties 1036
 interconnect challenges 1558
 internal robotics 1376
 international arbitrage, definition 1003
 international bimetalism, definition 1003
 international monetary system, definition 1003
 interoperability, definition 1282
 intron, definition 773
 intuitionistic defuzzification 970
 intuitionistic fuzzification 970
 intuitionistic fuzzy components, modification of 970
 intuitionistic fuzzy image processing 967
 intuitionistic fuzzy index, definition 973
 intuitionistic fuzzy set, definition 973
 inverse perspective mapping 843
 inverse perspective mapping (IPM), definition 847
 inverted index, definition 660
 isomorph (function), definition 1243
 isomorphic graphs, definition 709
 iSTART 1182
 iteratively reweighted least squares (IRL), definition 1144

J

Jacobians, definition 1087
 job arrival integration mechanism 857
 job elimination mechanism 857
 joint belief distribution 436
 joint camera calibration 843
 JONSWAP spectrum, definition 1608

K

Karhunen-Loeve, definition 553
 k-cross-validation, definition 560
 kernel density estimate, definition 909
 kernel estimator, definition 1350
 kernel machine, definition 1523
 kernel methods, definition 1523
 kernel trick, definition 1523
 kernel, definition 566
 kernelized fuzzy c-means (KFCM) 712
 KFM, definition 1218
 KGP agents 88
 KGP model 88
 Khepera robot 821
 Kirchhoff's Laws 1357
 k-lines 331
 K-nearest neighbour (KNN) 241
 K-NN, definition 566
 knowledge based robotics, definition 608
 knowledge discovery in databases (KDD), definition 891
 knowledge discovery, definition 487
 knowledge engineering 106
 knowledge engineering, definition 540
 knowledge extraction process 483
 knowledge extraction, definition 487, 588, 939
 knowledge management systems, procedural development 975–981
 knowledge management tool, definition 988
 knowledge management, definition 535, 988
 knowledge processing 926
 knowledge reduction, definition 1403
 knowledge society 532
 knowledge visualization, definition 787
 knowledge, definition 988

knowledge-based system, definition 995
 knowledge-based system, types of 990
 knowledge-based systems 989
 Kohonen maps 996
 Kolmogorov-Sinai entropy, definition 1272
 Kripke model, definition 1093
 Kullback Leibler distance (KL-distance), definition 1257

L

labeled transition systems, definition 1093
 Lagrange multiplier, definition 676
 LAMP 1612
 language model, definition 1472
 language recognition 179
 latent semantic analysis (LSA) 1254, 1257
 latent semantic analysis, definition 1184
 lattice gas automata, definition 360
 lattice theory, neural/fuzzy computing 1238
 lattice, definition 1111, 1243
 leaf node, definition 703
 learn to learn, definition 535
 learning (training) rule, definition 1063
 learning algorithm, definition 676, 1011, 1017
 learning algorithms for recurrent networks 1412
 learning design, definition 1282
 learning domain models 1026
 learning domain-specific planners 1025
 learning machine, definition 1466
 learning objects, definition 1282
 learning process 532
 learning rule optimization 577
 learning search control 1025
 learning stage, definition 866
 learning, active 1
 learning, game-based 140
 learning, mixed active 5
 learning, RETIN active 4
 learning, supervised 282
 learning-based planning 1025
 least mean square error reconstruction (LMSER), definition 901

- least squares support vector machine, definition 666
- least trimmed squares estimator (LTS) 1390
- least-squares algorithm, definition 742
- LEGO Group 1385
- LEGO MINDSTORMS robots 1385

 multiple dam scheduling 803
 multiple dam scheduling, definition 807
 multiple dam scheduling, harmony search for 803
 multiple layer perceptron (MLP), definition 1489
 multiple testing 66
 multiplexing (von Neumann), definition 479
 multiplicative monotonic cooling 345
 multi-scale transformation, definition 1111
 multivalued discrete neural model, definition 1120
 mutation 593
 mutation operator 651
 mutation, definition 595
 mutation, definition 653, 758
 mutual information projections, definition 909

N

Naïve Bayes classifier, definition 883
 Naïve Bayes classifier, improving 879
 naïve physics 334
 Naïve-Bayes, definition 546
 named entities 106
 named entity annotation 106

named entity recognition (NER) 1562
 nanoscale CMOS, definition 1481, 1561
 narrative information, definition 1172
 narratology, definition 1172
 n-ary languages, definition 1172
 NASA Robotics Alliance Project 1384
 Nash equilibria, non-cooperative games 1018
 Nash equilibria, software agents 1019
 Nash equilibrium, definition 1023
 natural language processing 1173–1178
 natural language processing 334
 natural language processing (NLP) 795, 1562, 1567
 natural language processing, definition 1184
 natural language understanding and assessment 1179
 natural language understanding and assessment, definition 1184
 natural languages 1174
 navigation, definition 1190
 negation, strong 1610
 negative filtering 180
 negative test predicate 180
 negotiation protocol, definition 1424
 negotiation strategy, definition 1424
 Nelder-Mead evolutionary hybrid algorithms 1191
 network lifetime, definition 758
 network visualization 782
 networks of evolutionary processors 1175
 neural architecture 1417
 neural classifier, definition 1496
 neural classifier, stream processing of 1490, 1497
 neural controller, definition 1101
 neural MREM model 1113
 neural network (NN) 554, 1424
 neural network based visual data mining 1205
 neural network framework (FNN) 32
 neural network, definition 1335, 1403
 neural network-based process analysis 1212
 neural networks and HOS 1226

neural networks, definition 423
 neural networks, in automated negotiations 1524–1529
 neural networks, multi-objective training 1152
 neural/fuzzy computing 1238
 neural-fuzzy systems (NFS) 32
 neurocomputing, and rich dynamics 275
 neuro-fuzzy system, definition 1403
 neuro-fuzzy technology 31
 neuro-fuzzy, definition 923
 neuromorphic modeling 223
 neuron model 639
 neuron model, definition 1017
 neuron modeling 1057
 neuron, definition 1481, 1561
 neurons 1558
 neutral decision, definition 1362
 new technologies feature 534
 new technologies proposal 533
 new technologies, definition 535
 new technologies, e-learning in 532
 Neyman-Pearson detectors 934
 n-gram model, definition 1472
 NKRL inference engine, definition 1166
 NKRL inference rules, definition 1166
 NKRL templates, definition 1165
 NLP techniques 1253
 NNs, learning techniques of 1435
 node, definition 703
 Nogood, definition 513
 noise 99
 noisy test categorization 100
 noisy text 99, 105
 noisy unstructured text data I 99–104
 non-cooperative facial biometric identification systems 1259
 non-cooperative games, definition 1023
 non-cooperative identification system, definition 1265
 non-membership function, definition 974
 non-monotonic adaptive cooling 347
 non-monotonic logic 331, 333, 1041
 non-monotonic reasoning paradigm 1370
 non-rigid objects 1363
 non-rigid objects, definition 1369
 note-taking techniques 337
 NP-hard problems, definition 1023

O

OAA approach 557
 object representation, definition 1369
 object tracking, definition 1369
 objective fitness function 592
 objective function, definition 1151
 odometry, definition 1087
 off-chip training, definition 839
 off-line system, definition 1454
 off-line writer identification system 1448
 Ohm's Laws 1357
 omnidirectional camera, definition 852
 omnidirectional vision 849
 on-chip training, definition 839
 one against all (OAA) model 556
 one against all approach, definition 560
 online learning, definition 1028
 online noisy documents 99
 on-line system, definition 1454
 ontologies for education 1278
 ontologies for learning design 1278
 ontology 1283–1289
 ontology alignment 1283–1289, 1290–1295
 ontology alignment systems 1285, 1290–1295
 ontology alignment techniques 1290–1295
 ontology alignment, definition 500
 ontology integration, definition 500
 ontology language, definition 1282
 ontology mapping techniques 495
 ontology mapping, definition 500, 1054
 ontology mediation, definition 500
 ontology merging, definition 500

 video image post-processing 385
 video-based face recognition 1455–
 1461
 videometrics 389
 videometrics, definition 389
 virtual and immersive environments,
 definition 540
 virtual reality, definition 1211, 1595
 virtual theatres, definition 540
 virtual, definition 535
 visual data mining 1205
 visual homing, definition 1190
 visual servoing, definition 847
 visualization methods 783
 vocabulary, definition 1473
 voice quality 1439, 1443
 voltage instability detection, using
 neural networks 1596–1602
 voltage output image processing
 1597
 von Neumann multiplexing 471
 Voronoi diagrams 12

W

wave flume 384
 wave flume experiments 383
 wave reflection at submerged break-
 waters 1603
 wavelet analysis, definition 1342
 wavelet transformation, mass spec-
 trometry 1338
 weak irrelevance of syntax (WIS)
 1373
 weak irrelevance of syntax, definition
 1375, 1432
 weak negation 1610
 wedgelet 223
 weight, definition 1011, 1017
 weighted clustering 592
 weights, evolution of 126
 Weka, definition 560
 wireframe model, definition 631
 wireless sensor networks (WSNs),
 genetic algorithms 755
 wireless sensor networks, definition
 758
 wireless sensor networks, genetic
 algorithms 756
 WoLF, definition 824
 word matching 1254
 word matching (WM), definition
 1258
 word-braker, definition 660
 WordNet 335

WordNet, definition 336
 Workflow Management Coalition
 (WFMC) 1615
 workflow management, based on
 mobile agent technology
 1615–1623
 World Health Organization(WHO)
 1589
 wrapper algorithm 635
 wrapper method, definition 638
 wrapper methods 635
 writer identification, definition 1454
 writer's off-line identification 1447
 WSNs, specific parameters 756

X

XML-RPC 1612

Y

Yellow Page, definition
 Yellow Pages 983, 988
 yield, definition 1481, 1561

Z

zygote, definition 382
 α -cut of a fuzzy set, definition 732
 δ band test, definition 1350
 ε -covering fuzzy partition, definition
 732
 χ^2 distance, definition 1035
